The Trivers-Willard (TW) hypothesis predicts that parent and offspring condition should effect the ratio of male/female offspring, but the validity and the exact causal mechanisms of this hypothesized relationship are still unclear.

Introduction

According to the Trivers-Willard (TW) hypothesis, offspring sex composition and parental investment postpartum may, under certain conditions, be biased toward either male or female offspring. Maternal and offspring condition play a decisive role in the following three assumptions underlying the TW hypothesis: First, maternal and offspring condition are correlated during the parental investment phase. Second, early offspring condition is correlated with offspring condition later in life. And third, males profit more than females from slight advances in condition in their reproductive success (Trivers and Willard 1973).

The question as to what indicators of maternal and offspring condition specifically are involved in modulating a possible TW effect is closely linked to the question of the specific mechanisms at play in sex ratio variation. Although the authors don't say much about mechanisms, they suggest that in species "in which males determine sex of offspring, female control of the sex ratio must involve differential mortality by sex" either of the sperm or at later stages during the parental investment phase (Trivers and Willard 1973, p. 91). The authors further suggest a few examples of physiological indicators of condition, e.g., health, strength, and body weight, as well as a number of indicators of environmental conditions, e.g., exposure to stressors, litter size, parity, and time of season, that may be relevant with regard to their hypothesis (*ibid.*). Yet, until very recently, little was known about the specifics of how a possible TW mechanism might operate.

The lack of a known mechanism and, in consequence, the lack of a clear specification of the relevant indicators for maternal and offspring condition might have contributed to the as of yet inconclusive state of the TW hypothesis (Cameron 2004; James 2012; Schnettler 2010). In recent years, researchers have tried to systematize findings on the statistical association between some measure of maternal condition and offspring sex ratios. Two meta-analyses, together covering about 400 empirical studies that examine the association between some measure of maternal condition and sex ratios in

various mammalian species, show that support for the TW hypothesis is stronger when maternal condition is measured at around the time of conception as opposed to a later time in the reproductive cycle (gestation, birth) (Cameron 2004; Sheldon and West 2004). This issue of timing has since been taken up by at least two studies examining the TW effect in humans. In one of these studies, based on a general population in Sweden, different timing of resource measurement led to the same conclusion: that there is a null effect with regard to the association between parental condition and sex ratios (Kolk and Schnettler 2016). The other study is based on a US elite sample and finds tentative evidence for a similar timing effect as one of the two meta-analyses elucidated (Schnettler 2013). Yet, in both of these studies, timing of resource measurement is rather coarse due to limited data availability on humans, as compared to the studies on other mammalian species.

The two meta-analyses mentioned above also evidence the breadth of condition measures that have been applied in research on the TW hypothesis so far. In addition to measures listed above, these include, e.g., mother's age, dominance status, food availability, time of insemination, and body weight (Cameron 2004). One of the two studies found that the correlation between maternal condition and sex ratios was stronger in studies that operationalized condition as a behavioral measure rather than a physiological one. Theoretically, the authors made sense of this finding by arguing that behavioral dominance may be a better predictor of future resource access than, e.g., current body weight, but also pointed out that an interaction between physiological and behavioral condition measures may exist that could not be tested in their meta-analysis and possibly complicates an empirical assessment of the TW hypothesis (Sheldon and West 2004).

Both a specification of the timing of maternal condition relative to the specific phase of parental investment and of measures used to proxy maternal condition help to narrow down the set of mechanisms driving a potential TW effect. In recent years, advances have been made in developing explanatory models on the potential

mechanisms responsible for sex ratio variation in response to various environmental influences, going beyond the scope of the TW hypothesis (see, e.g., Schnettler and Klüsener 2014). James (2008) has put forward the hypothesis that hormonal levels of both parents around conception affect sex determination preconception. In his research, he also links various environmental conditions (e.g., external stressors and toxic exposure) to varying hormonal levels, thus at least suggesting to close the theoretical gap between more distant measures of condition and physiological measures of condition directly involved in sex determination. Parental hormones also play a decisive role in a model put forward by Grant and Irwin (2009). Their model is at least in part supported by previous experimental research by the same two authors and suggests more specifically that the level of maternal follicular testosterone prior to conception affects the shape of the outer rim of the ovum and makes it more or less likely to later be fertilized by an X- or Y-chromosome-carrying spermatozoon. In addition to this mechanism around conception, their model further specifies that male fragility during the gestational period is another mechanism that affects sex ratios in a population, the latter being consistent with Trivers' and Willard's suggestion for a mechanism (see above). Taken together, their model allows one to reconcile some previously inconclusive findings on sex ratio variation by allowing that measures of condition may have different effects around conception and at later stages during the gestational period (Grant and Irwin 2009; Schnettler and Klüsener 2014).

Conclusion

In sum, various measures of condition have been employed in previous research on the TW effect, ranging from physiological measures that may be more or less directly involved in sex ratio variation to more distant environmental measures. The challenge in future research will be to elaborate on the causal pathways linking these different types of condition and how they are involved in the

hypothesized mechanisms. For studies examining the TW effect in human societies, where often some measure of socioeconomic status has been employed as a proxy for maternal condition, the challenge will be to examine how socioeconomic status affects physiological measures of condition. The null effect of a TW effect in a modern welfare state like Sweden (Kolk and Schnettler 2016) might well be due to the fact that differences in socioeconomic status are inconsequential with regard to physiological measures of condition, whereas in less developed societies, there might be a stronger connection between measures of condition that are more or less distant from the sex determination process.

Most of the above relates to the physiological part of the TW hypothesis and what maternal conditions might be driving this physiological effect. Much less is known about the behavioral part of the TW hypothesis in humans predicting sex-based favoritism in parental investment. The challenge here is larger, given that the potential causal pathways between indicators of condition and parental investment behavior may be strongly shaped, too, by other cultural and social influences on parental investment (Schnettler 2010). One potential mechanism linking maternal condition and maternal investment behavior that is discussed in the research literature is postpartum depression. The argument here is that postpartum depression can be seen as a withdrawal of maternal investment (Johns and Myers 2016).

Maternal Behavior

► Maternal Bonding

Maternal Bonding

Michael Numan

Department of Psychology, University of New Mexico, Albuquerque, NM, USA

Synonyms

Maternal behavior; Maternal love; Maternal motivation; Mother-infant attraction

Definition

The strong attachment of a mother to her infants, resulting in her caring for and protecting them, at least until they reach independence.

Introduction

Parental behavior is any behavior displayed by one member of a species toward an immature conspecific that increases the likelihood that the infant will survive (Numan and Insel 2003). Depending on the species, parental behavior can include maternal, paternal, and alloparental behavior (caretaking behaviors directed toward an infant other than one's own offspring). In mammals, the major infant-caretaking system is a uniparental maternal care system: In 95% of mammalian species, the postpartum mother is the sole caretaker of her offspring (Numan and Young 2016). In a small percentage of mammalian species, paternal and/or alloparental behaviors, in addition to maternal behavior, are essential for infant survival. Alloparental behavior occurs when older siblings, instead of dispersing, remain in the family group and help the mother care for her more recently born offspring (Numan 2015). Alloparental behavior can be divided into allo-maternal and allopaternal behavior, depending on the sex of the alloparent. Hrdy (2009) has hypothesized that allomaternal behavior was essential for infant survival during early human

evolution. The occurrence of paternal and alloparental behavior suggests that when such behavior is essential for infant survival within a social group, natural selection will create alternate mechanisms, which do not require pregnancy and parturition, to enable an individual to form a bond with an infant.

Hormones and Maternal Behavior

In most mammals, the physiological events of pregnancy and parturition influence brain mechanisms to activate maternal motivation (Numan and Insel 2003). This ensures that maternal behavior will be synchronized with the birth of the mother's young at a time when she is physiologically prepared to care for them, since many of these same physiological events also promote lactation. The essential physiological factors that activate the onset of maternal responsiveness at parturition include estradiol (a hormone secreted by the ovaries), prolactin and placental lactogens (hormones secreted by the pituitary gland and placenta, respectively), and the neuropeptide oxytocin, which is produced in the hypothalamus (the paraventricular nucleus) and is released into critical brain regions that regulate maternal motivation. In support of these findings, nulliparous females (females that have never given birth) in most mammalian species avoid and reject infants; they are not maternally motivated. Therefore, dual neural mechanisms regulate maternal behavior in most mammals: an inhibitory neural circuit that depresses maternal responsiveness in nulliparae and an excitatory neural circuit which promotes maternal motivation in the parturient female. The events of pregnancy and parturition have been proposed to depress the inhibitory circuit and activate the excitatory circuit (Numan 2015, 2017).

For many mammalian species, the physiological events that trigger the onset of maternal behavior at parturition are no longer essential for its maintenance during the remainder of the postpartum period (Numan and Young 2016). After a sufficient amount of postpartum maternal experience, it is likely that synapses become strengthened within certain key brain circuits so that maternal behavior can continue without hormonal

and oxytocin stimulation. These neural changes solidify an enduring mother-infant bond.

These results imply that there are neural mechanisms which can regulate mother-infant attraction in the absence of continued hormonal and neuropeptide influences. This fact may be relevant to the evolution of alloparental behavior. For example, a nulliparous allomother is maternally motivated and attracted to young conspecifics, suggesting that the inhibitory circuit is not active and the excitatory circuit is active in the absence of pregnancy and parturition. A good example of allomaternal behavior occurs in nulliparous marmoset monkeys (a New World primate species). These females remain in their family group after they are weaned, and they help their mother care for more recently born infants (Hrdy 2009). Although these allomothers are not lactating, they can help carry the mother's young offspring, and as these younger offspring grow older, the allomother can also provision them with easily digestible food items. The following evolutionary scenario can be proposed: For those species where alloparental behavior is adaptive, being important for infant survival in an extended family group, the mechanisms regulating attraction and bonding to infants may have become relatively emancipated from the need for stimulation by the physiological events of pregnancy and parturition. That is, the neural circuits regulating attraction and bonding to infants may have evolved to allow infant stimuli to gain direct access to these circuits in the absence of pregnancy and parturition, although the release of oxytocin in the brain, in the absence of pregnancy and parturition, may be involved in the initial attraction of an allomother toward infants (Numan and Young 2016). Since alloparents are caring for their younger siblings, kin selection mechanisms may be involved in this evolutionary process.

Since allomothering has been proposed to be important for infant survival during early human evolution (Hrdy 2009), the processes described above may account for the fact that human maternal motivation is relatively emancipated from hormones and that nulliparous women can adopt offspring and show normal maternal behavior. This hypothesis does not rule out the likelihood that an allomother's continued interaction with

young infants improves her allomaternal behavior and further solidifies the bond between the allo-mother and the infant she is caring for (Stolzenberg and Champagne 2016).

The Brain and Mother-Infant Bonding

There are evolutionary conserved core neural circuits that underpin maternal motivation in all mammalian species, including humans (Dulac et al. 2014; Numan 2017; Numan and Insel 2003). A key component of these circuits is the medial preoptic area (MPOA), located in the anterior part of the hypothalamus. Depression of MPOA activity suppresses maternal behavior, and estradiol, prolactin, placental lactogens, and oxytocin act on their receptors in MPOA to stimulate the onset of maternal behavior. Importantly, MPOA inactivation also eliminates allomaternal behavior (Numan and Young 2016). Research has shown that the MPOA interacts with the mesolimbic dopamine (DA) system to regulate a mother's attraction to her offspring (Numan 2015, 2017; Numan and Young 2016). The mesolimbic DA system includes DA neurons in the ventral tegmental area (VTA) of the midbrain that project to the nucleus accumbens-ventral pallidum (NA-VP) circuit in the forebrain. The mesolimbic DA system has been referred to as the brain's reward system and is involved in regulating an organism's attraction to a variety of rewarding stimuli. MPOA activation of the mesolimbic DA system endows infant stimuli with rewarding properties which promotes infant-seeking and infant-caretaking behaviors in the mother. This basic subcortical circuit (MPOA–VTA–NA-VP) is not only involved in mother-infant attraction in animals; fMRI research shows that this system is also active in human mothers that view infant stimuli while they are in an fMRI scanner (Atzil et al. 2017; Numan 2015, 2017). Particular synapses within this circuit probably become strengthened during mother-infant interactions, so that the mother-infant bond becomes solidified, allowing it to endure over long periods of time, even in the absence of continued hormonal stimulation (Numan 2015, 2017; Numan and Young 2016).

Animal studies have focused on subcortical mechanisms in the control of maternal motivation. These studies deal with the behavioral attraction of mothers to their infants, and animal studies cannot deal with maternal feeling states. However, in humans, feelings of love toward one's infant – maternal love – clearly influence maternal behavior. A lack of love for one's infant could lead to neglect and even abuse of the infant. Most fMRI research on feeling states in humans has focused on cortical areas and has correlated activity within the orbitofrontal and insular cortices with a variety of feeling states, including empathy (Numan 2015, 2017). Importantly, neural activity increases in these regions when mothers view infant stimuli and report positive feeling states (Numan 2017). Significantly, the orbitofrontal and insular cortices project to the medial prefrontal cortex, which, in turn, projects to MPOA. This could be a neural route through which maternal love influences maternal behavior in humans (Atzil et al. 2017; Numan 2017).

The Development of Maternal Behavior

Children who have been abused and/or neglected by their parents tend to become abusive or neglectful parents toward their own offspring, and experimental studies on nonhuman mammals, including primates, have confirmed that this relationship is a causal one (Numan 2015, 2017). A variety of mechanisms are involved in how exposure to abuse and/or neglect causes an infant to develop faulty maternal behavior in adulthood, and gene-environment interactions are involved (Numan 2015, 2017). With respect to the core circuits that regulate maternal motivation in animals, it has been shown that the way a mother treats her infants influences the development of the MPOA and its interactions with the mesolimbic DA system (Stolzenberg and Champagne 2016). Therefore, when a young infant is exposed to poor maternal caretaking, the core maternal neural circuits are negatively impacted, and this may be one of many routes that underpin the intergenerational continuity of abnormal maternal behavior. There is also preliminary evidence for humans that poor parenting influences the

development of orbitofrontal/insular cortex projections to the medial prefrontal cortex and MPOA in the affected offspring, which could interfere with the subsequent translation of maternal love into maternal motivation (Strathearn et al. 2009).

Maternal behavior not only influences the development of maternal behavior in her infants but also influences broader aspects of the infant's emotional and social development (Numan 2015). Therefore, an understanding of how faulty maternal behavior affects the development of offspring has wide-ranging significance.

The Neural Systems Underlying Mother-Infant Bonding May Provide a Foundation for Other Strong Social Bonds

Since the maternal care system is a primordial aid-giving system that is present in all mammals, it may have provided the neural foundation for other types of prosocial behaviors that rely on strong social bonds.

Most mammals are non-monogamous, and the female is the sole caregiver to her offspring. However, about 5% of mammals are monogamous. In monogamous species, the mated pair remains together after mating, forming a pair bond, and the male may also engage in paternal behavior. Numan and Young (2016) have compared the neural circuits that regulate the mother-infant bond and the pair bond (the strong attraction of members of the mated pair to one another), and they noted similarities in the underlying neural circuits. Since the strong attraction of a mother to her infants is common in all mammals, whereas monogamy is rare, it was proposed that the neural mechanisms underlying the mother-infant bond may have been modified by natural selection to establish the capacity to develop pair bonds under the particular ecological conditions where monogamous mating strategies are adaptive.

In behavioral studies on nonhuman and human primates, Burkart et al. (2014) have provided further evidence for the proposal being offered here.

They designed a test for unsolicited proactive prosociality which examined whether individuals within their social groups would provide fellow group members with food without obtaining food for themselves and without being solicited to provide such aid. They found that the extent of alloparental behavior within primate groups was an excellent predictor of the distribution of proactive prosociality. Proactive prosociality occurred at high levels in those primate groups that also displayed alloparental behavior but was low or absent in those species without alloparental behavior.

Perhaps alloparental care is linked to the evolution of hyper-cooperation within certain primate groups because, as an initial step, the evolution and development of "trust" in infants toward alloparents were adaptive (Hrdy 2009). But the high level of prosociality in species with alloparents may also be related to the degree to which the maternal care neural system evolved to become a relatively open system, allowing social stimuli from other group members, in addition to those from infants or a mate, to gain access to this caregiving/bonding system in the absence of pregnancy and parturition: The neural basis of alloparental behavior may have served as a preadaptation that allowed for the evolution of strong caregiving bonds between all members within certain social groups.

Conclusion

Understanding the mother-infant bond provides a window into how the most basic social bonding system operates. By understanding its neural mechanisms and how the system can be influenced by physiology, experience, and genetics, we gain an understanding into how abnormal maternal behavior may develop, which in turn influences child development. Such an understanding could give rise to remedial therapies. Finally, understanding the mother-infant bond gives us insight into the mechanisms underlying the formation of other strong social bonds between members of a social group.

Definition

Grandparental investment includes all resources (e.g., time, care, help, money) that grandparents allocate to their offspring. Typically, the maternal grandmother invests more resources in her offspring than other grandparent types (i.e., maternal grandfather, paternal grandmother and paternal grandfather).

Introduction

Robert Trivers' (1972) theory of parental investment applied Hamilton's (1964) general rule to parental behavior. Parental investment theory considers the investments that parents make in their offspring and can easily be extended to

grandparental investment, but to gain the same fitness advantage, grandparents should invest in a larger number of children than the parents do. Humans are cooperative breeding species, meaning that mothers have always needed some alloparents (or allomothers) to help take care of an infant or to help the mother acquire food (Hrdy 2009). These caretakers often include the child's father, older siblings, aunts and uncles, and grandparents, especially the maternal grandmother.

Due to paternity uncertainty and sex-specific reproductive strategies, all grandparents are not in an equal position relative to their grandchildren (Euler and Weitzel 1996). Paternity uncertainty means that women can be sure that the child they gave birth to is biologically related to them, but men can never be 100% certain that the child is actually theirs. The link between parental investment and relationship certainty is evident in many species and males in several species invest in their offspring accordingly as a function of paternity certainty (Platek and Shackelford 2006). Although human males often invest in their offspring, they too have potential uncertainty in their relationship to their children.

In the case of grandparents, no uncertain links of paternity exist between grandchildren and maternal grandmothers. Paternal grandfathers are in the most uncertain position because they have two uncertain links of paternity between them and their grandchildren. Therefore, maternal grandmothers are predicted to invest in their grandchildren the most and paternal grandfathers will invest the least (Euler and Weitzel 1996). In addition, evolutionary researchers have explained women's stronger involvement in kin relations by sex-specific reproductive strategies, which means that due to biological, psychological, and cultural reasons, women tend to invest more in their kin than men (Coall and Hertwig 2010).

Empirical Evidence

One of the most common findings in grandparent studies is that the maternal grandmother usually

invests the most, followed by the maternal grandfather and the paternal grandmother, but the paternal grandfather usually invests the least (see Coall and Hertwig 2010 for review). This is true even in countries where no explicit preference for matrilineal family relations is evident and when many potentially confounding factors such as the age and the health of a grandparent or the geographical distance between a grandparent and a grandchild are controlled for (Danielsbacka et al. 2011). However, cultural traditions and norms can confound the grandparental investment pattern. In patrilocal societies, paternal grandparents are found to invest more in their grandchildren than maternal grandparents (e.g., Kaptijn et al. 2013; Pashos 2000).

A matrilineal bias that is found in many studies may also be enhanced because of the gatekeeping role of parents. Gatekeeping refers to the fact that parents guard access to a grandchild and, subsequently, the quality of the dyadic parent-grandparent relationship becomes important. Studies have shown that the dyadic relationship between mother and daughter is typically closer than other dyadic relationships between parental and grandparental generations, which may further increase the investment made by the maternal grandmother (Danielsbacka et al. 2015).

Conclusion

Alloparenting is an important feature of human species. In historical and traditional populations and in contemporary societies, one of the most important alloparents has been the maternal grandmother. Several studies from contemporary Western societies have shown that maternal grandmothers invest the most in their grandchildren of all grandparent types.

Definition

Maternal investment involves the provision of resources that provide for the basic needs of offspring.

Introduction

The construct of parental investment was first introduced by Trivers (1972), whose predictions were based on processes that began in our distant evolutionary past. He proposed that mothers served their own reproductive interests best by providing high levels of care to offspring. The proposals made by Trivers were extended by the work of Daly and Wilson (1988), who observed the discriminative levels of care shown to offspring by mothers, whereas males were relatively more concerned with procreating. In both cases, parents were more likely to invest resources in children to whom they were biologically related (Daly and Wilson 1988). However, mothers who gave birth could be certain that the newborn was their own child whereas fathers did not share that same degree of certainty. The resources potentially available to parents in contemporary times include economic resources, social support from others, and time available to spend with offspring.

Researchers focusing on mothers were concerned with the combined effects of maternal resources and the probability that a child would survive. Daly and Wilson (1988) proposed that mothers invest more in low-risk than high-risk children if they have low resources to share across current or future offspring. Low-risk children, in turn, are more likely to reach adulthood and have offspring of their own. In contrast, mothers with high resources can afford to invest in high-risk as well as low-risk children.

Daly and Wilson (1988) observed that children who give cues to some kind of health problem or physical abnormality at birth are more likely than other children to be abandoned at birth. However, of the two conditions, higher levels of rejection occur when the child has a highly visible physical abnormality (Weiss 1994).

Contingent Model of Maternal Investment

There has been emerging evidence that are circumstances in which some mothers invest disproportionately high in high-risk offspring. Bugental and Beaulieu (2003) proposed a contingent model of parental investment in which (1) parents with low resources invest more in low-risk children whereas (2) parents with high resources invest more in high-risk children. In support of the basic nature of this model, Davis and Todd (1999) demonstrated that when food is scarce, the final brood size of birds is optimized if mothers feed the largest chick first, but if food is plentiful, the final brood size is optimized when the mother feeds the smallest chick first. The authors noted the same contingent feeding pattern has been found with actual birds, e.g., pied flycatchers.

Evidence for the proposed contingent model of parental investment comes from many sources. For example, Schepher-Hughes (1985) found that parents in areas characterized by extreme poverty (low resources) were observed to withhold food from sickly children but feed healthy children.

Empirical Test of the Contingent Model of Maternal Investment

In the first test of the contingent model with mothers and children, Beaulieu and Bugental (2008) assessed the resources that depressed mothers versus nondepressed mothers were willing to allocate to a high-risk or a low-risk child. As predicted, depressed mothers (conceptualized as having low attentional resources) invested more in a full-term infant whereas nondepressed mother invested more in a preterm infant.

Bugental et al. (2010) made an experimental test of the contingent model with human mothers. Mothers of preterm versus full-term infant were recruited to participate in a 3-year program. They were randomly assigned to one of three conditions: (1) a condition in which a home visitor provided direct help and guidance to mothers for 1 year, (2) a cognitive reframing condition in which mothers were assisted in solving caregiving

problems on their own for 1 year, and (3) a control condition. Child health was measured when children reached 3 year of age. As predicted, mothers assigned to the cognitive reframing intervention invested more time in the care of at-risk children than low-risk children, which in turn predicted higher levels of health.

The preferential investment in high-risk children among parents with high resources (and reduced investment in low-risk children) optimizes the possibility that both will survive to adulthood. The high-risk children might not survive without additional help; however, the low-risk children are likely to survive with some reduction in parental help. Thus the predicted and observed pattern is consistent with an evolutionary perspective.

Physiological Processes in Maternal Investment

Increasing attention has been given to the role of physiological processes in the early relationship between nonhuman mothers and their offspring. Early awareness of this relationship emerged in the work of Michael Meaney and colleagues. For example, Francis et al. (1999) observed that rat pups who received low licking and grooming at an early age were fearful in novel settings whereas those who received high levels of licking and grooming did not show this response. Associated changes were found in the functioning of the amygdala, a brain that is influenced by stress. In order to remove the effects of shared genetics, rat pups were cross-fostered at birth by an unrelated mother. As a broader conclusion from Meaney's program of research, animal research has demonstrated the clear effects of the postpartum behavior of mothers on brain development, stress reactivity, and capacity for social affiliation.

Research has been conducted on oxytocin for both humans and other species. This hormone plays a role in social bonding at many stages of life but is particularly pronounced in bonding relation between mothers and offspring. The program of research conducted by Feldman and colleagues (e.g., Feldman et al. 2007) has

demonstrated the pronounced effect of oxytocin on maternal behavior and subsequent behavior of the child. For example, higher prenatal levels of the maternal oxytocin present prenatally were found to predict high postnatal maternal bonding behaviors such as gaze, positive affect, unique vocalizations, and affectionate touching.

Conclusions

Variations in maternal investment in their offspring show regularities across measures, cultures, and species. The majority of research has approached this basic process from an evolutionary framework. More recent research often addresses the issue of biochemical mediators. The general conclusion is that maternal responses to the young influence their later behavioral and affective responses – a process (barring pathology) that is typically adaptive.

Maternal Malnourishment

Nikki Clauss and Ashley Rankin
Oklahoma State University, Stillwater, OK, USA

Introduction

Malnourishment occurs when the body becomes deficient in macronutrients and/or micronutrients. Maternal malnourishment, in particular, appears to be an informative indicator of environmental conditions that has a profound impact on a developing fetus.

Thrifty Genotype

The undernourished fetus of a malnourished mother undergoes metabolic adaptations that

enhance its immediate survival chances (Hales and Barker 2001). Alterations in muscle mass, hepatic structure, and hormone receptor density can all lead to these adaptations becoming permanently fixed and referred to as a “thrifty phenotype.” If the postnatal conditions match the prenatal conditions, these adaptations can be advantageous. However, if there is a mismatch between postnatal conditions and prenatal conditions, such as abundant food sources, the adaptations of the “thrifty phenotype” can be maladaptive.

Parent-Offspring Conflict

Parent-offspring conflict is an idea that was first introduced by Trivers (1974) and can be useful in understanding the alteration of brain growth during fetal development resulting from maternal malnourishment. The idea of parent-offspring conflict is that offspring may be selected to take more from a parent than the parent is selected to give. This period of conflict begins during the prenatal period and lasts throughout childhood and adolescence. During fetal development, this conflict is centered around the transfer of nutrients from the mother to fetus (Haig 1993). Pregnancy is energetically costly, and when food is scarce, a mother will only transfer as much energy to her fetus as she can while maintaining her energy reserves for future reproduction. This occurs even at the risk of a reduction in the likelihood of offspring survival. This phenomenon is apparent when optimal versus actual birth weights are compared. In the majority of human populations studied, the birth weight that is optimal for neonate survival is greater than actual mean birth weights (Frisancho 1993). Early pregnancy, without malnutrition, may also create conflict. For example, teenage mothers are themselves growing, which leads to a competition between them and their fetuses for nutrients (Wu et al. 2004). Thus, in undernourished and in very young mothers, there is an upper limit placed on the amount of energy the fetus can receive from the maternal host, and the rate at which that energy is transferred from the mother to fetus is also influenced by an interaction between maternal and fetal hormones.

Growth Programming

Maternal nutritional intake is not a direct cause of fetal growth rate (Rosso and Salas 1994). Instead, fetal growth rate appears to be determined by the mother’s nutritional state at conception, before the fetus is large enough for its growth to be nutrient-dependent. Indeed, in animal studies, rats which were malnourished before gestation produced offspring with reduced brain volume and DNA content (Harding and Johnston 1995). It is also difficult to increase fetal growth rates once they have been established by the mother’s nutritional state at conception (Rosso and Salas 1994). For example, newborns born to mothers who are malnourished at conception, but have high-energy intakes during pregnancy, will still be underweight. Alternatively, a woman who is in good physical condition who experiences malnutrition during the first half of her pregnancy can still produce normal weight offspring as long as she recovers before the second half of her pregnancy. However, birth weight is more directly nutrient-dependent during the second half of pregnancy, so birth weight will be affected by the mother’s malnutrition during this time.

Maternal Malnutrition and Fetal Brain Development

Nutritional or growth programming of a fetus of an undernourished mother has consequences that extend beyond prenatal life and into adulthood. These consequences include the increased risk of diabetes, hypertension, and other diseases (Lukas and Benjamin 1999). Brain sparing is believed to underlie the phenomenon of growth programming (Barker 1995). Maternal malnutrition leads to the developing fetal organs competing over limited nutrients. In a nutrient-lacking prenatal environment, the size and functioning of most individual organs are sacrificed, but only to the extent to which that sacrifice does not threaten the survival of the organism (Sibly and Calow 1987). Because the brain is an organ that is metabolically expensive and critical to survival, it is a privileged organ that is spared to a great extent (Klingenberg and Nijhout 1998). The heart is also spared to a much

lesser extent. For example, there is a significant size reduction in the liver and thymus of small-for-term infants, while the heart is slightly enlarged and the brain is much larger compared to the rest of its body. Thus, brain growth is maintained through a reduction in visceral mass, and the heart is maintained to supply nutrients to the brain (Lukas and Benjamin 1999).

Conclusion

Maternal nutrition status at conception is a major component of fetal growth trajectories (Rosso and Salas 1994). Therefore, maternal malnourishment at conception often leads to poor fetal growth. Parent-offspring conflict (Trivers 1974) provides a useful framework in which to understand the impact that maternal malnutrition has on the developing fetus. The flow of energy from the undernourished mother to the fetus is limited to ensure the continued reproductive fitness of the mother, sometimes at the expense of the fetus (Sibly and Calow 1987). To increase chances of survival, fetal organs compete for nutrients, resulting in the developing fetal organs being reduced in size and function to better support the developing brain. This adaptation can be advantageous in postnatal life if the child is born into a food-scarce environment (Hales and Barker 2001). However, if the environment is food abundant, the adaptation has the potential of leading to several health problems, making it maladaptive.

Introduction

Maternal care is essential for the survival of human offspring as humans are not able to care for themselves for several years after their birth. Several studies have found that mothers are emotionally closer to their offspring than fathers are and that mothers invest more resources in their offspring than fathers do. Theories in evolutionary psychology posit that this increased care comes from women's natural tendency to nurture and cooperate with others, and this increased investment stems from the fact that women begin biologically investing in their offspring immediately after conception.

Tend and Befriend

In the human ancestral environment, men often hunted for food, while women stayed back and remained with their group to help care for each other and their offspring. This behavior among women helped develop strong emotional connections, reciprocally altruistic behaviors (e.g., food sharing, caring for each other's children, etc.), and cooperative social alliances. This phenomenon has become known as *tend and befriend* – the idea that women respond to stress and obstacles in their environment by tending to oneself and her offspring and befriending others so as to maintain a social network of trusted individuals who can aid in the tending process (Taylor et al. 2000).

Evolution of Maternal Role

The hunter-gather environment was organized in a manner that may have positively selected for cooperative and nurturing behaviors (i.e., tend and befriend) in women. Therefore, it is not

surprising to see that women are usually more nurturing toward their offspring than men. On average, mothers are significantly emotionally closer, and give more care, to their offspring than fathers do (Buss 2000). This is partly explained the mothers' genetic certainty – the idea that because the mother carried and gave birth to the offspring, she is certain that the child is hers (Maestripieri and Mateo 2009).

Women invest significantly more resources in their offspring than men. This is apparent from conception. Once the female's ovum becomes fertilized by the male's sperm, the woman immediately begins investing in the offspring in the form of gestation. The woman must increase her caloric intake – which required more resources – and must care for her body and baby to ensure the health of the unborn offspring. This investment – which takes place before the offspring is born – requires a series of resources, including time (i.e., 40 weeks of gestation), increased food intake, monetary costs of doctor's appointments, and attention to harmful teratogens (things that may harm the offspring in the womb, such as alcohol and caffeine) in one's environment to avoid (Buss 2000). There are also many costs associated with pregnancy – discomfort, severe pain, gestational diabetes and other disorders, death, and many others. Therefore the mother has already invested a vast amount of resources in the offspring before it is ever born. Whereas, theoretically, by this same time, the only investment that the male has to make is the amount of time and energy it took him to help conceive the child. This increased investment also leads to greater maternal care toward the offspring. In short, because they have already invested more, they continue to invest and care more (when compared to fathers). This increased maternal care continues throughout the offspring's development.

Conclusion

Ultimately, the maternal role is usually considered to be a nurturing role. This corroborates the evolutionary psychological evidence which supports

the idea that women may have evolved tendencies to nurture and cooperate with other people. This tendency toward nurturance, coupled with the immense amount of resources that mothers must expend for the sake of their child's survival and development, has produced a strongly nurturing maternal role in humans.

Synonyms

Caregiving sensitivity; Maternal competency; Maternal responsiveness; Parental sensitivity; Sensitive mothering

Definition

A mother's (or any caregiver's) ability to perceive and correctly interpret their infant's signals (e.g., distress, need, social) and then respond to them in a prompt and accurate manner.

Introduction

Maternal sensitivity is one of the key determinants of child outcomes with its vast influence on the way the child learns to perceive and react to the world. Massive empirical work, starting with Ainsworth's seminal Uganda study (1967), has reliably linked maternal sensitivity to infant attachment patterns. Caregiving sensitivity should be considered not only as a trait characteristic of the parent but as a dynamic collection of behaviors that are attuned to the infant's changing needs. These behaviors are orchestrated to react to the needs of the infant in a sensitive and consistent manner while interacting with them. A sensitive caregiver is able to constantly recognize the changes in the infant's physical and psychological needs, attend to these needs in a way that supports the infant's use of the caregiver as a safe haven (i.e., whom the infant can turn to for support and comfort in times of distress) and secure base (i.e., from whom the infant can explore and learn about the world and develop their own personality), and reiterate if the infant is not soothed. What is more, in addition to engaging in prompt and appropriate behavioral responses to infant needs, sensitive caregivers also function as translators between the infant and the environment they cannot yet master on their own. Hence, the quality of sensitive caregiving is directly related to how the child comes to experience the world. In the following sections, first the antecedents and consequences of maternal sensitivity will be discussed, then the measurement techniques that are used for quantifying maternal sensitivity will be explained, and finally the intervention studies aiming enhancing maternal sensitivity will be elaborated.

Antecedents and Consequences

Maternal sensitivity was empirically studied for the first time by Ainsworth et al. (1978) via home observations. Ainsworth and her team then went on to investigate the relationships between maternal sensitivity and infant attachment by the strange situation procedure (SSP), where the infants were observed for their reactions to episodes of separation from and reunion with their mothers in the lab. The researchers assessed a variety of maternal behavior on four rating scales tapping into the sensitivity, acceptance, cooperation, and accessibility of the mother, which were identified to be strongly correlated with the attachment style of the infant as measured in the SSP. Since this pivotal study, numerous empirical studies have consistently reported moderately strong links between caregiving sensitivity and infant attachment security (see de Wolff and van IJzendoorn 1997 for a meta-analysis). Sensitivity, therefore, appears to be a crucial factor in understanding the development of individual differences in the formation of attachment bonds. Caregiving sensitivity has also been identified to be related to a wide array of other crucial developmental outcomes, such as executive functions, behavioral problems, sleep quality, and even body mass index (see Booth et al. 2018 for a review).

It is worth noting that the association between caregiving sensitivity and infant attachment is significantly weaker in studies with low SES or clinical samples (de Wolff and van IJzendoorn 1997), suggesting sensitive caregiving may be superseded by suboptimal child-rearing environments and stressful living conditions. Supporting these conjectures, in their recent review, Booth et al. (2018) show that contextual stress is one of the most important determinants of caregiving sensitivity. Specifically, unfavorable socio-demographic ecology (e.g., low income, low maternal education, young age of parenting, absence of the infant's father), perceived parenting stress, maternal internalizing symptoms (e.g., depressive symptoms), and anxiety have been strongly associated with reduced levels of maternal sensitivity.

Infant characteristics and temperament also play an important role in the degree of caregiving

sensitivity. Sensitive parenting can be harder to achieve with infant negativity, whereas an infant who manifests positivity can be easier to sensitively respond to. Supporting these conjectures, Mills-Koonce et al. (2007) found that the level of caregiving sensitivity decreases for all mothers at high levels of infant negative effect (e.g., prolonged crying, intense protest, venting).

Measurement

Measurement techniques aiming to assess caregiver sensitivity typically derive the sensitivity ratings from direct observations of caregiver-child interactions. These observational tools can be used to assess the quality of sensitive care provided to the child by any caregiver.

The first empirical tool used for these observations was the Ainsworth's Maternal Sensitivity Scale (AMSS) (Ainsworth et al. 1971). The AMSS involves coding several behaviors such as affective expression, appropriateness, and amount of physical contact in a variety of settings (e.g., play, feeding, teaching) on four global scales: *sensitivity* (i.e., the extent to which the mother responds promptly and appropriately to the child's signals), *acceptance* (i.e., how much the mother values the child's will), *cooperation* (i.e., whether the mother's interventions are minimally intrusive), and *accessibility* (i.e., the extent to which the mother is psychologically available as needed). The AMSS can be conducted in the house or laboratory, and it typically takes between 25 min and 2 h to complete.

Another common tool for assessing maternal sensitivity is the Maternal Behavior Q-Sort (MBQS) (Pederson et al. 1990). The MBQS is based on Ainsworth's work, but it concentrates the evaluation of the mother's behavior into 90 items that assess her accessibility, responsiveness, and promptness to the child's needs. Using a card sorting technique, trained raters observe the mother and then classify and rate these 90 behaviors in terms of the frequency she engages in them. The scores are then correlated with expert-based prototypic scores for ideal maternal sensitivity, and the resulting correlation coefficient is used as the global maternal sensitivity score of the mother. The MBQS can be conducted in the house, playground, or laboratory

and is usually filmed. It typically takes between 40 min and 2 h to complete.

Intervention Studies Aiming Enhancing Maternal Sensitivity

As the links between caregiving sensitivity and developmental outcomes have become clearer with amounting empirical studies, intervention efforts in enhancing caregiving sensitivity have increased over the last decades (see Bakermans-Kranenburg et al. 2003; Mountain et al. 2017 for reviews). These early intervention studies typically target caregivers with infants less than 3 years of age and are carried out as home visiting programs where the parents are trained on how to synchronize their behaviors with their infant's needs and develop attachment relationships. These studies have been shown to reduce insensitive parenting and infant attachment insecurity. Not necessarily too lengthy but intensively scheduled interventions with precise behavioral focus are more effective in augmenting sensitivity and attachment security. Intervention programs have also been shown to have long-lasting effects on other crucial child outcomes, such as lessened internalizing and externalizing behaviors, and improved social and linguistic competence.

Conclusion

Maternal sensitivity is one of the central caregiving characteristics that has profound and long-lasting effects on child outcomes; hence, it merits the attention of all scholars interested in child development, parenting, and attachment. It is highly related with the resources a caregiver possesses, and it is a skill that can be enhanced with training. Therefore, efforts toward enriching the parenting environment and educating caregivers are invaluable in improving child development.

Maternal-Fetal Conflict

Scott Forbes

Department of Biology, University of Winnipeg,
Winnipeg, MB, Canada

Synonyms

Genomic imprinting; Imprinted gene; Maternal-embryo conflict; Matrigene; Parent-offspring conflict; Patrigene

Definition

In humans, genetic conflicts between mothers and embryos may generate phenotypic conflicts, such as gestational diabetes and preeclampsia, which appear to be pathological, but instead arise from differing optima over the preferred level of maternal investment in the offspring.

Introduction

Mothers and their embryos live in intimate though not always harmonious contact during gestation. As Robert Trivers (1974) noted, parents and offspring have shared, but not identical, genetic interests. This asymmetry creates the potential both for conflict and cooperation, and there are circumstances where offspring may be more self-ish than their parent's desire: this is the concept of parent-offspring conflict.

A fundamental conflict arises over how maternal resources are allocated. An increased transfer of maternal resources to the current offspring may impair her ability to invest in other contemporary or future progeny. In humans, the potential for maternal-fetal conflict is heightened by the almost

unparalleled access the embryo enjoys to maternal physiological systems. It is clear that a certain times and places, embryos are able to wrest at least partial control of maternal endocrine systems to the benefit of the embryo and detriment of the mother. The most obvious examples are gestational diabetes and preeclampsia (high blood pressure during gestation) that induce obvious harm for mother. More subtly, embryos may have stolen control of the maintenance of pregnancy from mother via the secretion of counterfeit hormones into the maternal bloodstream. Recent work suggests that there may also be maternal-fetal conflict over thyroid function during pregnancy, and that cognitive disorders such as autism and schizophrenia may arise when genetic accidents favor one side in the tug-of-war between mothers and their embryos.

Some of the most conspicuous maternal-fetal conflicts involve genomic imprinting, where gene expression is conditional on parent-of-origin. These make up a small fraction (~1%) of genes within the human genome but are strongly implicated in a variety of maternal pathologies. Under the kinship theory of genomic imprinting (Haig 1993, 2004), genes of paternal and maternal origin within the embryo are engaged in a tug-of-war over the transfer of resources from mother to embryo, with paternal origin genes favoring greater investment and maternal origin genes resisting. Imprinting involves the silencing of genes depending upon whether they originated from mother or father. As with most parent-offspring conflicts, a pro rata compromise between maternal and paternal interests is the expected result (Haig 1993, 1996, 2004; Mock and Parker 1997), with a rough balance established between the two. But genetic anomalies that generate a maternal or paternal bias in the expression of imprinted genes often reveal the underlying conflict between mothers and their embryos, and in particular between maternal and paternal interests, resulting in conspicuous imprinted gene disorders.

Parent-Offspring Conflict

Parent-offspring conflict theory predicts that parents and offspring will often disagree over the

level of resources an offspring should receive (Trivers 1974). Who wins or loses will rest upon who holds the power in the relationship. If power is shared, the resolution is normally expected to be a pro-rata compromise between the two parties (review in Mock and Parker 1997). In the context of fetal-maternal relations during human pregnancy, it was long assumed that mothers were in complete control. She provided resources to her progeny in a cooperative partnership with her offspring. And even if a fetus desired more than mother was prepared to give, a placental barrier stood between them. How could an offspring act upon its desires? This idyllic view of harmonious relations has been revised in light of both theoretical and empirical work showing that embryos often disagree, sometimes strenuously, with maternal processes. Moreover, they hold the power to enforce their will, sometimes with demonstrable, and occasionally even fatal, consequences for their mother (see “Fatal Conflicts” below). Embryos actively manage the gateway between themselves and their mothers at the placental interface. They are able to ship materials across the placenta into the maternal bloodstream and, in doing so, are sometimes able to “persuade” mothers biochemically to act against maternal interests.

Terminology

A fetus is usually defined as the offspring once all major organ systems are complete, toward the end of the first trimester (8–11 weeks post conception). The embryo is an earlier stage of development that follows the conceptus (the fertilized egg), arising after gastrulation once the tissue layers have differentiated into ectoderm, mesoderm, and endoderm. There are no clear dividing lines among the conceptus, embryo, and fetus because development is a continuum.

The following provides a précis of the key events in early gestation. A more detailed description can be found in Haig (1993). Following fertilization, cell division occurs and at 5–9 days post-conception, a hollow ball of cells, the blastocyst, is formed. It is the blastocyst that implants in the uterine wall, and a process of decidualization

commences around this time. The uterine endometrium thickens, and secretory glands enlarge and become functional; the decidua, so named because this tissue is shed with the placenta at birth, becomes increasingly vascularized being infused with coiled spiral arteries.

The blastocyst contains an inner cell mass that will differentiate into the embryo proper and, an outer cell layer, the trophoblast, that will form the extra-embryonic membranes including the chorion. The trophoblast penetrates the maternal uterine wall, forming chorionic villi that invade the uterine decidua, anchoring the embryo and forming the vascular connections needed for nutrient absorption and gas exchange. The trophoblast eventually breaches the walls of the maternal arteries and veins, and a system of internal cavities forms that fills with maternal blood fed by the spiral arteries. The trophoblast replacement of maternal cells in the spiral arteries reduces mother’s ability to control blood flow through the placenta. In this hemochorial placentation, maternal blood is in direct contact with the embryo’s chorion, giving the embryo direct access to maternal systems. The placenta is a composite of tissue of offspring (trophoblast) and maternal origin (the decidua). Hemochorial placentation is considered the most invasive form of placentation among mammals (Crespi and Semeniuk 2004). A deep trophoblast invasion of maternal tissue increases access of the fetus to maternal resources. Conversely, a shallow placental invasion is associated with subsequent pathophysiology, most notably preeclampsia (Steeger et al. 2010). The placenta is a temporary organ that is key to fetal growth and development. It is built for the exchange of nutrients, gases, hormones, cytokines, immune system components, intact cells, and cellular components and waste products. Importantly, as we shall see below, it is a major endocrine organ affecting both fetal and maternal physiology.

Maternal-embryo or maternal-fetal conflict can occur at every stage of gestation. Here I shall use the term embryo for early gestation and fetus for later gestation, and shall apply the terms maternal-embryo and maternal-fetal conflict interchangeably.

How Embryos Manipulate Mothers

Historically the maternal-fetal interface at the placenta was considered a passive barrier. It is now recognized, however, that there is a considerable transport of materials from fetus to mother and vice versa across this so-called barrier. Fetal cells, cellular debris, hormones, cytokines (proteins involved in cell signaling), microRNA, micro-somes, and exosomes (extracellular vesicles that carry a variety of cargo) all make their way into maternal circulation. In some cases, this may be material that is shed inadvertently into mother's bloodstream, but in other cases, it appears to be anything but accidental. Rather, embryos are attempting to co-opt entirely maternal decisions about provisioning the embryo.

The view of the passive placental "barrier" has been supplanted by the growing recognition that the trophoblast, an extraembryonic tissue of offspring origin, actively regulates the transport of materials across the placenta. Given the more-or-less direct access of the embryo to the maternal bloodstream via its hemochorial placenta, this anatomical arrangement opens the door to fetal manipulations of maternal systems, and the fetus does exactly that using multiple pathways. These include the use of materials shed or secreted into the maternal bloodstream including hormones, cytokines, DNA, RNA, fetal/maternal cells and cell components, and materials packaged inside vesicles.

Hormones and Fetal-Maternal Conflict

Haig (1993, 1996) was the first to suggest that embryos used hormones secreted from the trophoblast to manipulate their mothers during gestation, and introduced the new term "allocrine" to describe a hormone produced by one individual to affect the endocrine system of another. Given that an embryo has the same complement of genes as mother, any time a maternal hormone operates and endocrine system, an embryo can produce the same hormone potentially for its own benefit. Human chorionic gonadotropin appears to be one such example: it appears to have supplanted

maternal luteinizing hormone in corpus luteum "rescue" that is necessary for the maintenance of pregnancy during the first trimester of gestation.

Maternal-Fetal Conflict and Microchimerism

That trafficking of cells occurs between fetus and mother during gestation is now widely recognized. The flow of cells is bi-directional, though more fetal cells are transferred to mother than vice versa (Boddy et al. 2015). Fetal cells remain present in mothers (fetal microchimerism) long after pregnancy, in some cases are found decades later. Some fetal cells yield clear benefits for mother. Fetal stem cells, for example, have been found to aid in wound healing and the repair of cardiac tissue. But fetal cells may also impose costs for mothers, manipulating maternal systems for fetal gain.

Fetal cells are found routinely in the breast, thyroid, and brain, where they could play a role in increasing offspring access to maternal resources – e.g., by shifting the release of hormones toward the offspring optimum (Boddy et al. 2015), but as yet direct evidence is lacking. A maternal immune system response to the presence of fetal cells in the brain has been postulated to contribute to the inflammation linked to postpartum depression, but again direct evidence is lacking.

Maternal cells are also transferred to the fetus via the placenta and during breast-feeding. This maternal microchimerism creates the potential both for cooperation and conflict (Boddy et al. 2015). For example, the transfer of immune system elements to the offspring during breast-feeding is likely beneficial, but the same pathway could be used to manipulate progeny for maternal interests.

Non-coding RNA and Fetal Maternal Conflict

Non-coding RNA (RNA not translated into a protein) plays a key role in gene regulation and

provides another pathway for embryos to manipulate maternal systems. There are a variety of non-coding RNA's with different functions, but much recent work has focused on the role of microRNAs (miRNA) in human pregnancy.

MicroRNA was first discovered in the 1990s, but it was not until the early 2000s that their key role in gene regulation was identified. About 1000 microRNAs are known, and they target the majority of human genes. Individual miRNA can have multiple gene targets. MicroRNA are short (19–24 nucleotides long), single-stranded RNAs that act as negative regulators of gene expression by binding to messenger RNA to prevent protein translation. They can down-regulate a gene by suppressing it directly or suppressing a promoter for a gene. Or they can up-regulate gene expression, a gene by suppressing a repressor for a gene.

Two large imprinted clusters of miRNA genes, on Chromosomes 14 and 19, are directly relevant to maternal-fetal conflict. The Chromosome 19 microRNA cluster (C19MC) is imprinted and expressed from genes of parental origin. The C19MC arose within the primate lineage, and its relatively recent origin suggests that it may have been important in the development of the invasive hemochorial placentation shared among humans and the great apes (Noguer-Dance et al. 2010). The C19MC consists of ~46 tandemly repeated microRNA genes encoding 56 miRNAs. These are expressed primarily in the placenta but are also found in tumors (Noguer-Dance et al. 2010; Flor and Bullerdiek 2012). The C19MC miRNA mediates a variety of biological processes including cellular proliferation and invasion, inflammation and apoptosis, and are important in growth and invasion of the embryonic trophoblast into maternal tissue.

One recently established effect of C19MC miRNA is the upregulation of maternal autophagy. Autophagy is a catabolic cellular pathway that is used to recycle damaged or unneeded cellular components and to clear pathogens. Experimental work has shown that C19MC miRNA increases resistance to viral infection (Bullerdiek and Flor 2012). From the perspective of fetal-maternal conflict, it would appear that embryos,

by secreting miRNA to upregulate the maternal immune system, are promoting their own protection, perhaps against maternal interests. Given that they are of placental origin, it is not surprising that C19MC miRNAs are eliminated from the maternal bloodstream following birth (Donker et al. 2012).

The C14MC is another large gene cluster coding for miRNA located in an imprinted gene domain on Chromosome 14 (Morales-Prieto et al. 2013). The C14MC originated within the mammals well before the origin of the C19MC. C14MC miRNAs are maternally expressed, and some, but not all, are expressed primarily in the placenta. C14MC miRNA plays a variety of roles including neurogenesis and embryo development. Interestingly, the C14MC is the largest cluster of tumor suppressor genes. Conversely, the C19MC miRNAs are associated with tumor development. Given the similarity in molecular pathways shared between tumor development and the invasion of embryonic trophoblast into maternal tissue (Haig 2015), an obvious inference is that C14MC and C19MC miRNAs sit on opposite sides of a fetal-maternal conflict over trophoblast invasion, with greater invasion being favored by paternally inherited genes from the C19MC and restraint favored by maternally expressed genes from the C14MC.

Once produced, placental miRNAs can be packaged in exosomes that are cell-derived vesicles that can be used for the transport of a variety of materials, and exported into the maternal bloodstream.

Maternal-Fetal Conflict and Genomic Imprinting

For most genes in the human genome, the parent of origin has no effect on the action of the gene. But for a small proportion, roughly 1% overall with higher proportions in the placenta and developing brain, it matters a great deal whether the gene originated from mother or father. These are the imprinted genes. Whether the gene is active is conditional upon the parent of origin. A consequence of this genomic imprinting is that

the gene is expressed from only one of the two alleles present, with the other being silenced epigenetically. Genes from mother when found in the embryo are referred to as matrigenes or madumal alleles, and patrigenes or padumal alleles when obtained from father. Under maternal imprinting, the matrigenes are silenced; with paternal imprinting, the patrigenes are silenced. As seen below, imprinted genes are hotbeds of maternal-fetal conflict.

How Are Genes Silenced?

Gene silencing associated with imprinting is achieved via reversible epigenetic mechanisms that include DNA methylation, histone modification, non-coding RNA that regulate gene function, or long-range chromatin interactions (Monk 2015). In many cases, an imprint is established early (during gamete formation) and maintained over the entire lifespan. In other cases, the imprinting pattern is complex, and a specific gene may, for example, be imprinted and expressed from just one allele at certain times and in certain tissues (often the placenta) but be expressed from both alleles elsewhere.

Genomic Imprinting Is Revealed by Genetic or Epigenetic Accidents

In many cases, the evidence of genomic imprinting is concealed by outcome of the tug-of-war between maternally and paternally imprinted genes with the end result being that neither side holds a decisive advantage. The underlying conflict, however, is revealed when a genetic or epigenetic accident tips the balance in one direction. Errors in the establishment of epigenetic marks, or errors in gamete formation, may result in an over or underexpression of alleles of maternal or paternal origin.

Uniparental disomy is one such mechanism. In the absence of imprinted genes, it should not matter if both chromosomes derive from the same parent. But when imprinted genes or gene clusters are present, it matters a great

deal. Uniparental disomy is thought to result from a corrective mechanism to repair trisomies in the earliest stages of gestation. Errors in meiosis sometimes result in extra copies of chromosomes in gametes. Trisomy 21 or Down syndrome is the most common trisomy at birth. In some cases, an initial trisomy is corrected post-zygotically by deletion of one of the supernumerary chromosomes. But in one in three cases (if chromosomes are deleted randomly), this deletion will result in both chromosomes coming from the same parent: a uniparental disomy. If both chromosomes are paternal in origin, this will result in an overexpression of any paternally expressed imprinted genes (patrigenes); and a maternal overexpression if both chromosomes are from mother (matrigenes). Uniparental disomies are often associated with imprinted gene disorders. An overexpression of paternal genes in uniparental disomy of chromosome 15 results in Prader Willi syndrome (Haig 1993). Angelman syndrome is the result if uniparental disomy of chromosome 15 stemming from two maternal chromosomes.

Why Genomic Imprinting?

A variety of hypotheses have been proposed to explain the origin and maintenance of imprinted genes (Holman and Kokko 2014). To date, there is no single hypothesis that provides a comprehensive explanation for the origin and maintenance of genomic imprinting, but the kinship theory (Haig 2004) has garnered the most empirical support and is directly applicable to fetal-maternal conflict.

The kinship theory posits that genomic imprinting arose as a result of competition between the maternal and paternal genomes over the provisioning of the offspring (Haig 1993, 1996, 2004). It builds upon Trivers' (1974) concept of parent-offspring conflict but looks at it from the more focused perspective of genes of maternal and paternal origin in the embryo. In species that are not strictly monogamous, patrigenes and matrigenes will have differing optima for the optimal level of maternal

investment in the offspring. Matrigenes are equally related to all of mother's offspring, present and future. Patrigenes, except in cases of strict life-long monogamy, are not. As a result of this relatedness asymmetry, patrigenes favor a greater investment of maternal resources in the current offspring than matrigenes.

The result is a physiological and developmental tug-of-war between genes of paternal and maternal origin in the embryo, with consequent effects on mother. Patrigenes favor a greater transfer of resources from mother to embryo, resulting in greater fetal growth; maternal genes favoring a more constrained transfer of resources and lower fetal growth. Imprinting is a mechanism to manage the underlying sexual conflict between genes of paternal and maternal origin. Genes that increase the transfer of resources from mother to fetus are maternally imprinted, and expressed from the paternal copy only. Genes that constrain the transfer of resources are paternally imprinted and expressed from the maternal copy only. The canonical example of an imprinted gene is insulin-like growth factor 2.

An Example of Imprinted Genes

Insulin-like growth factor 2 (Igf2) and its receptor (Igf2r) were the first imprinted gene loci to be described in mice. Igf2 acts as an embryonic growth enhancer, allowing nutrients to diffuse across the placenta. It is active (in both mice and humans) from the patrigene. The matrigene, conversely, is silenced by methylation. In mice, the receptor, Igf2r, is also imprinted and is active from the matrigene only. The receptor effectively serves as a growth regulator by capturing and degrading insulin-like growth factor 2. This diametric gene pair accords with the kinship theory where patrigenes favor greater, and matrigenes lesser, investment in the embryo.

The story is slightly more complex in humans as the receptor gene (IGF2R) is not consistently imprinted, being expressed from both alleles in most individuals. In humans, it is a different gene that acts antagonistically toward the paternally expressed IGF2: the H19 gene. H19 is a gene for

a long non-coding RNA that regulates IGF2 in both humans and mice: it is associated with reduced fetal mass and cell proliferation, is imprinted, and is maternally expressed. Similar to the Igf2-Igf2r dyad in mice, the IGF2-H19 dyad in humans is engaged in a physiological tug-of-war, with paternally active genes acting as growth enhancers, maternally active genes acting as growth suppressors.

Maternal-Fetal Conflict over Implantation

An embryo's success in implantation affects profoundly its later access to maternal resources and is where maternal-fetal conflict begins. The process is normally governed by a complex dialog between mother and embryo involves both the immune and endocrine systems results: it is a chemical discussion that sometimes descends into argument. The notion that it is a mutually beneficial dialog and negotiation is almost certainly a too sanguine view of maternal-fetal relations. It is not even clear that implantation requires maternal consent, as illustrated by the ability of the embryo to implant successfully at ectopic sites (Haig 2015). As such, successful implantation can be viewed as sitting somewhere between a maternal-fetal collaboration and a constrained parasitism of mother by embryo.

Preparation for this interaction begins before fertilization takes place, and well before if it is to be maximally successful. A successful pregnancy requires a state of active immune tolerance of foreign paternal antigens of the conceptus. Immunosuppressive regulatory T cells (T_{regs}) are central to this process. Prior exposure to semen and seminal fluid via coitus and/or oral sex plays a key role in inducing maternal immunological protection of the embryo via the production of T_{regs} (Robertson et al. 2009; Robertson and Sharkey 2016). The evidence is manifold and the incidence of preeclampsia (high maternal blood pressure during gestation) serves as a biomarker of an initial conflict between mother and embryo over the depth of implantation, as preeclampsia is associated with a shallow implantation.

Preeclampsia is more common in first pregnancies; it is linked to the period of cohabitation involving unprotected sex between woman and man; the incidence of preeclampsia rises if a woman changes partners; oral sex with the father is protective against preeclampsia but only if there is exposure to seminal fluid. A clear role of the immunological preparation for paternal antigens is revealed with assisted reproduction where donor sperm and/or eggs are used. The background rate of preeclampsia is roughly 1 in 20 to 1 in 12 pregnancies, but this rises to about 1 in 6 if donor sperm are used. That figure soars to 1 in 3 if both donor sperm and egg are used. From these data, it is tempting to suggest that the link between the period of cohabitation involving unprotected sex, and subsequent preeclampsia, is an index of an evolved mechanism whereby mothers can modulate investment in an offspring, investing more if paternal care is likely. Such a suggestion is obviously conjectural.

Maternal-Fetal Conflict over Spontaneous Abortion

Mothers use spontaneous abortion as a mechanism of quality control for the genetic defects that are surprising common in human embryos (Haig 1993; Forbes 2017). Though common at conception, major genetic defects are rare at birth. Depending on maternal age, somewhere between half and 99% of conceptions are spontaneously aborted, and most major chromosomal defects are lost early in gestation, often before a woman is aware that she has been pregnant, if only for a short time.

Haig (1993) suggested that mothers and embryos may disagree over whether pregnancy should continue, with mothers setting a more stringent standard for quality control than embryos, and that a placental hormone, human chorionic gonadotropin (hCG), has played a key role in this maternal-embryo conflict (see Forbes 2017 for a recent review).

During the first trimester of pregnancy, a continued production of the hormone progesterone by the corpus luteum (the structure that forms from

the follicle after release of the ovum) is necessary for pregnancy maintenance. The corpus luteum, in turn, is maintained by a glycoprotein hormone. In many eutherian mammals, that is luteinizing hormone (LH). But in primates, that function has been usurped by chorionic gonadotropins produced in the placenta. In humans, this corpus luteum “rescue” is performed by placentally produced hCG. In the ancestral condition, where maintenance of the corpus luteum was controlled by maternal LH production from the anterior pituitary, mothers could discontinue pregnancy by shutting off LH production, which in turn shuts down progesterone production, resulting in spontaneous abortion.

hCG is a counterfeit hormone produced by embryos to replace maternal control of the corpus luteum. Haig argues that mother and fetus may “disagree” over the whether pregnancy should continue. For example, mothers are predicted to prefer a higher threshold for offspring quality than embryos. Selection would favor embryos to secrete hCG thereby maintaining progesterone production and to escape spontaneous abortion. The initial step appears to have been the placental (embryonic) production of LH when hemochorial placentation first emerged in the anthropoid primates. Hemochorial placentation allows the embryo direct access to the maternal bloodstream and first appears in the tarsiers. Earlier primates had an epitheliochorial placenta. The difference is two additional tissue layers standing between the embryo and the maternal bloodstream, the uterine epithelium, and maternal vascular endothelium. These extra tissue layers stand as a barrier to the free flow of large macromolecules such as LH or hCG into the maternal bloodstream. In short, embryos cannot easily tamper with maternal physiology.

All that changed with the emergence of hemochorial placentation in the tarsiers, monkeys, and apes. Now embryos could use placental LH to wrest control of the corpus luteum away from mother. The expected coevolutional response from mother would be to raise the threshold level of LH needed to maintain the corpus luteum, and thus begins an evolutionary arms race. The next step appears to have been a

duplication of the key LH gene, in particular the gene producing the beta chain of LH that confers functionality in this glycoprotein hormone family. This duplication gave rise to the first chorionic gonadotropin. The expected maternal countermeasure would be to raise the threshold level of hormone production necessary to maintain pregnancy ever further, which in turn favors an increased hormone production by the embryo in an escalating arms race. There is genetic evidence of exactly that. There have been not one but six gene duplications in the primate lineage to create a family of chorionic gonadotropin genes, and in humans the production of hCG is so prodigious during early pregnancy that it spills into the urine where it forms the basis of pregnancy tests (Haig 1993).

hCG and Maternal-Fetal Conflict over Thyroid Function

Human chorionic gonadotropin plays a variety of roles during gestation beyond just corpus luteum rescue. It is often referred to as the hormone of pregnancy and is detectable even before implantation occurs. Measurement of the level of a hyperglycosylated variant on the day of implantation accurately forecasts subsequent spontaneous abortion (review in Forbes 2017). hCG effectively serves as the Swiss army knife of the endocrine system, and it even serves as a bridge between the endocrine and immune systems.

hCG is part of the glycoprotein hormone family that also includes thyroid stimulating hormone (TSH), follicle stimulating hormone, and luteinizing hormone. It cross-reacts with the receptors for these other hormones because of its strong similarity in molecular sequence. It reacts weakly with the TSH receptor, but is produced in such large quantities that it plays a key role in maternal thyroid function during pregnancy. Forbes (2014) suggests this dual control of the maternal thyroid may result from maternal-fetal conflict over the production of thyroid hormone essential for neuro-muscular development of the embryo.

Iodine is a key micronutrient necessary for the production of thyroid hormone, and thyroid

hormone is necessary for brain development (review in Forbes 2017). It is unusual among micronutrients in that there is very little somatic storage. It must continuously be replenished from the maternal diet. Iodine demands rise sharply during gestation, which is especially important in iodine-deficient populations. Most humans over most of human evolutionary history have lived in conditions of iodine deficiency. As recently as 1970, before the advent of universal salt iodization, 2/3 of the world's population lived under conditions of iodine deficiency, and even today, iodine deficiency remains the single greatest source of preventable cognitive impairment.

Although embryos require iodine and thyroid hormone for neurodevelopment, release of their limited supply has heavy long-term costs for mothers, including thyroid disease and later subfertility or infertility. Embryos appear to use hCG production to maintain maternal thyroid hormone production to secure access of maternal iodine. Pregnancy sickness, long associated with hyperthyroidism, may arise as a by-product of maternal-fetal conflict over thyroid function. An extreme form of pregnancy sickness that affects roughly 1% of pregnant women is hyperemesis gravidarum. It is an intractable form of pregnancy sickness that extends well past the first trimester of pregnancy and often requires hospitalization (Verberg et al. 2005). It results in maternal dehydration and malnutrition, and, if untreated, is sometimes fatal.

Though the etiology of pregnancy sickness is still unclear, it has long been linked to hCG production, and its incidence mirrors the production of an inert metabolite of thyroid hormone (Forbes 2014, 2017). Mothers suffering from hypothyroidism, and incapable of producing sufficient levels of thyroid hormone to generate this metabolite, do not exhibit pregnancy sickness.

Beyond its role in corpus luteum rescue and maternal thyroid function, hCG provides a bridge between the immune and endocrine systems. It is key to creating a tolerant micro-environment at the fetal-maternal interface through its effect on attracting immunosuppressive T_{regs} and influencing their function

(Robertson et al. 2009). This is key during the in process of embryo implantation and plays a role in another maternal-fetal conflict over maternal provision of the embryo: preeclampsia.

Maternal-Fetal Conflict and Preeclampsia

Preeclampsia is a hypertensive disorder of pregnancy where maternal blood pressure is dangerously elevated. It affects 5–8% of pregnancies and is a leading cause of both fetal and maternal mortality and morbidity (Steegers et al. 2010). Preeclampsia is associated with a shallow trophoblast invasion of the maternal decidua, resulting in a reduced fetal access to maternal resources. Embryos by increasing maternal blood pressure to increase access to resources. Under Haig's (1993, 1996) kinship hypothesis, preeclampsia can be viewed as a fetal countermeasure to an initial loss in the initial immunological battle over the depth of implantation.

The etiology of preeclampsia is complex and not fully understood. However, a clear role for imprinted genes is emerging. Recent work shows that paternally expressed imprinted genes are upregulated in preeclampsia, and maternally expressed genes are downregulated (Christians et al. 2017); moreover, imprinted genes are more likely to be dysregulated in preeclampsia than randomly selected genes. These data are consistent with the kinship theory of genomic imprinting, where paternally inherited genes favor greater investment in the offspring than maternally inherited genes.

Increasing maternal blood pressure is one fetal tactic employed in maternal-fetal conflict over the transfer of maternal resources from mother to offspring: another diabolical tactic is making mother temporarily diabetic.

Maternal-Fetal Conflict and Gestational Diabetes

Gestational diabetes mellitus, hereafter “gestational diabetes” is a metabolic disease that affects roughly 1 in 7 pregnant women (Buchanan and

Xiang 2005). It is similar to Type 2 diabetes in that it features insulin resistance (the presence of insulin fails to reduce blood glucose following meals) and glucose intolerance (blood glucose levels remain elevated following meals). Gestational diabetes functions as fetal tactic to increase access to maternal resources by increasing fetal access to glucose (Haig 1993, 1996).

The main conflict occurs in the third trimester over the optimal level of blood glucose with embryos favoring a higher threshold level to enhance resource uptake. The pathophysiology of gestational diabetes is largely unknown, but is clearly complex. Placental hormones appear to induce higher maternal blood glucose, but that fetal tactic is opposed by a higher maternal insulin production. That maternal response is in turn countered by further fetal manipulations to induce insulin resistance and increase insulin clearance – e.g., via placental enzymes to degrade insulin; placental insulin receptors to act as an insulin sink (Haig 1993, 1996). Both mothers and fetuses exposed to gestational diabetes are at greater risk for Type 2 diabetes later in life.

As with preeclampsia, there appears to be an immune-system link to gestational diabetes (Shober et al. 2014). Dysfunctional immunosuppressive T_{regs} appear to undermine the normal maternal immune suppression necessary for pregnancy establishment and maintenance in gestational diabetes. Elevated levels of inflammation appear to interfere with insulin signaling, leading to insulin resistance.

Fatal Conflicts

An enigmatic feature of maternal-fetal conflict is that it sometimes results in the death of mother, and consequently her fetus, that obviously is in the interest of neither party. Preeclampsia that serves to increase fetal access to maternal resources by elevating maternal blood pressure and placental perfusion is across the globe, a leading cause of maternal morbidity and mortality (Steegers et al. 2010). Hyperemesis gravidarum, a rare extreme form of pregnancy sickness, may be fatal if untreated (Verberg et al. 2005).

Such lethal outcomes reduce the fitness of both parties and should be selected against. How then could they arise? Why is it unclear but three possibilities that are not mutually exclusive seem likely: (1) rare maternal deaths may be a cost counterbalanced by net benefits that accrue to the embryo; (2) embryos make the best of a bad situation by adopting high-risk high-reward tactics; and (3) the mechanism used by the embryo to manipulate maternal physiology is imperfectly calibrated because the intervention occurs outside the normal negative feedback control circuit.

Haig (1993) suggested that maternal-fetal conflict over hCG production may have driven an escalated evolutionary arms race with alternating bouts of elevated hormone production by the embryo countered by greater maternal resistance to their effects. As Haig notes, arms races usually end when it is too costly for one or both parties to continue. A series of gene duplications have led to human chorionic gonadotropin being produced in staggering quantities in the placenta, with pregnancy sickness a by-product. Most cases of pregnancy sickness subside after the first trimester of pregnancy with little demonstrable long-term cost for either mother or fetus. However, in rare cases of hyperemesis gravidarum, there are marked costs for both mother and embryo, including occasional maternal/fetal death (Verberg et al. 2005).

Here we might use the analogy of a cliff edge. Natural selection will push offspring toward greater selfishness until the costs of such selfishness (maternal morbidity and mortality) exceed the benefits (enhanced growth and survival of the offspring). This leaves both parties near the cliff edge. All biological systems are subject to variation that stems from a variety of sources: developmental, environmental, or genetic. It may simply be the extreme of this natural range of variation that results in a small proportion of maladaptive, fatal outcomes. Both mother and fetus fall from the cliff.

With preeclampsia, it appears that offspring make the best of a bad situation: a shallow implantation in the maternal decidua and limited access to maternal resources. Their solution? A high-risk strategy: elevating maternal blood pressure by biochemical manipulation. Again, it is not in the

interest of the fetus (or mother) to push mother over the edge of the cliff, as they will fall with her. But the fetus may not be able to gauge in real time how close to the edge of the cliff they are. Quite possibly the fetus may lack access or the capacity to monitor mother's current physiological state accurately resulting in missteps that precipitate a fall over the cliff edge.

A further complication is that the fetal intrusion into maternal physiology occurs outside the normal control circuit. For example, maternal thyroid function is normally governed by a negative feedback loop: thyroid stimulating hormone increases thyroid hormone production, that in turn regulates thyroid stimulating hormone secretion. The fetus co-opts maternal thyroid function from the outside, injecting hCG into this maternal thyroid control circuit. As hCG interacts with the TSH receptor, it pushes maternal thyroid hormone production higher, which in turn reduces TSH production. But it has no effect on the production of hCG that is manufactured in the placenta. There is no obvious feedback loop between maternal physiological state and fetal hCG production: that may be by design. Modulating hCG production using maternal cues potentially opens the door to maternal manipulation of fetal production of hCG. Instead, hCG production may be relatively inflexible and not subject to fine-tuning based upon the current maternal physiological state. Again, such a system may be more prone to occasional missteps and maladaptive falls from the cliff.

Maternal-Fetal Conflict and the Social Brain

Though imprinted genes make up roughly 1% of the human genome, they are abundantly expressed during brain development. Recent work suggests that imprinted genes and an underlying maternal-fetal conflict may affect human cognition. The normal tug-of-war between genes of maternal and paternal origin is an integral part of normal cognition, but when the balance is tipped in either direction, cognitive disorders are the result.

Crespi and Badcock (2008) suggest that psychosis and autism represent opposite extremes on a cognitive continuum with normality at the center. Autism is associated with underdeveloped social cognition. Psychosis, conversely, is associated with overdeveloped, dysfunctional social cognition. They further suggest that perturbations from normality are associated with the developmental and metabolic effects of imprinted genes acting in the placenta and brain. Patrigenes contribute to autistic-spectrum disorders whereas matrigenes contribute to psychotic spectrum disorders.

There are multiple risk factors for autism, including environmental, hormonal, and genetic effects, but most cases are of unknown origin. Badcock and Crespi (2006) first suggested that a paternal bias in the expression of imprinted genes was associated with some cases of autism. This led to the complementary suggestion that imprinting in the opposite direction – a maternal bias – would have the opposite effect – e.g., paranoia and related psychotic and mood disorders, and the genesis of the diametric disorders hypothesis.

Diametric Imprinted Gene Disorders

Under the “diametric disorders” hypothesis (Crespi and Badcock 2008), autistic features will be inversely correlated with schizotypal features (schizophrenia, bipolar disorder, and major depression). Prader-Willi syndrome and Angelman syndrome accord with this hypothesis. Prader-Willi and Angelman syndrome are diametric disorders associated with the same imprinted gene cluster on Chromosome 15. Prader-Willi syndrome results from a biased expression of matrigenes; Angelman syndrome from patrigenes.

Prader-Willi syndrome is associated with an elevated incidence of psychosis in adulthood, especially when it is associated with uniparental disomy (review in Crespi and Badcock 2008). Conversely, Angelman syndrome is associated with an elevated incidence of autism and autistic-like syndromes. This pattern accords with the hypothesis of dysregulated imprinted genes, maternally biased with Prader-Willi

syndrome and paternally biased with Angelman Syndrome (Badcock and Crespi 2008).

Crespi and Badcock (2008) suggest that there are two major axes of cognition: the first is determined by the sex of the focal individual. The second is whether there is a paternal or maternal bias in the expression of imprinted genes. They suggest that more common but less severe cognitive disorders occur when the two axes are aligned – i.e., male with paternally biased expression of imprinted genes; female with maternally biased expression of imprinted genes. If the two axes are mismatched, less common but more severe disorders are observed. Autism is less common but tends to be more severe in females; schizophrenia is less common but tends to be more severe among males.

Badcock and Crespi (2008) themselves note that “to propose a single overriding explanation for such a huge range of mental conditions is controversial.” Nevertheless, the explanatory framework that integrates evolutionary biology with psychiatry, psychology, and neuroscience provides new insights and makes testable predictions. Strong tests will require identification of the specific imprinted genes involved and the mechanisms of action. Such work is beginning: Crespi et al. (2018) identified an altered expression of two brain-expressed imprinted genes with paranoid thinking. The traits included imagined and delusional thoughts, actions, and plans, all consistent with a paranoid subtype of schizophrenia. Crespi et al. suggested that small maternal biases in brain-expressed imprinted genes may result in a beneficial increase in theory of mind cognition (i.e., the ability to attribute mental states to oneself and others), but large maternal biases are associated with a pathological, hyper-developed theory of mind, resulting in paranoia.

Maternal Fetal Conflict and Autophagy

The C19MC microRNAs are strong candidates for involvement in maternal-fetal conflict. They are of recent origin in the primate lineage and expressed in the placenta and in tumors. That they are imprinted and paternally expressed

makes them prime suspects as cellular trouble-makers. They are involved in a wide array of processes including trophoblast invasion, immunoregulation (Noguer-Dance et al. 2010; Donker et al. 2012; Morales-Prieto et al. 2013), and experimental work has shown that C19MC miRNAs increase resistance to viral infection (Bullerdiek and Flor 2012).

C19MC miRNAs are also known to upregulate maternal autophagy via miRNA exported into the maternal bloodstream in exosomes (Delorme-Axford et al. 2013). Autophagy (=“self eating”) is a cellular pathway that is used to recycle damaged or unneeded cellular components and to clear bacterial and viral pathogens. It has been described as a double-edged sword, beneficial in some contexts but harmful in others (Shintani and Klionsky 2004). Autophagy allows, for example, the survival of cells in the nutrient poor conditions of a tumor. Given the similarity in molecular mechanisms used by cancer cells and invasive trophoblast (Haig 2015), it is reasonable to suspect that embryos may upregulate autophagy against maternal interests during trophoblast invasion of maternal tissue. Autophagy is also upregulated during periods of nutritional stress, being used as a form of self-cannibalism to redeploy cellular building blocks such as amino and nucleic acids. One might reasonably suspect that embryos upregulate autophagy to gain greater access to nutrients, again against maternal interests. Embryos might also prefer a greater level of autophagy that their mothers as protection against viral or bacterial pathogens; mothers might bear long-term costs associated with autophagy, such as neurodegeneration, or autoimmune dysregulation, not similarly borne by the placenta that is in effect a disposable organ. Although maternal-embryo conflict over autophagy seems plausible, especially given the involvement of imprinted genes, it remains conjectural awaiting further study.

Maternal-Fetal Conflict and Cancer

The similarity between cancer and invasive trophoblast has been known for more than a century

(review in Haig 2015). The challenge in both cases is similar: Mothers and their embryos “disagree” over the optimal access of the embryo to maternal resources, and embryo interests are served by a deeper trophoblast invasion of maternal tissue, and use a variety of biochemical mechanisms to overcome maternal resistance. Invasive cancers face the same physiological challenges and, not surprisingly, use similar biochemical pathways. Many cancers express trophoblast specific genes; hCG, the hormone of pregnancy that also plays a key immunomodulatory role, is considered a cancer biomarker (Haig 2015). And intriguingly, there is a paternal bias in the expression of imprinted genes active in invasive cancers (Summers et al. 2002), as expected under the kinship hypothesis if trophoblastic genes are being retasked in invasive tumors. And as noted above, just as autophagy is upregulated during pregnancy by paternally expressed miRNA of trophoblastic origin, autophagy is upregulated in tumors to facilitate cell survival in nutrient poor conditions.

Conclusion

The view that pregnancy is a harmonious collaboration between mother and fetus has given way to the view that both parties have differing agendas based upon shared but not identical genetic interests as first suggested by Robert Trivers (1974). The discovery of genomic imprinting in the 1990s added a further layer of sexual conflict to potential maternal-fetal conflicts via disagreements between genes of paternal and maternal origin in the embryo, with paternal genes favoring a greater transfer of maternal resources than genes of maternal origin. This conflict perspective (Haig 1993) has helped to explain a variety of otherwise puzzling apparent pathologies of pregnancy, for example, preeclampsia, gestational diabetes, autism, and schizophrenia. The end result of a coevolutionary battle of maternal and paternal interests in the fetus is often expected to be a pro rata compromise with a balanced outcome of the normal result: imprinted genes are one potential outcome. Mothers have been

selected to silence copies of genes that increase the transfer of resources from mother to embryo. Fathers have been selected to silence of copies of genes that decrease that transfer. The underlying conflicts are sometimes revealed, however, and pathologies the outcome, if the balance is disturbed by genetic or epigenetic accidents resulting in a paternal or maternal bias in gene expression.

Definition

Competition among members of the same sex for reproductive partners, opportunities, and resources.

Introduction

Darwin's (1872) theory of natural selection posited that organisms must compete not only for survival but also to reproduce. Through reproduction, organisms then transmit their genetic material to offspring. In sexually reproducing species, organisms must compete with other members of their sex to mate with those of the opposite sex. Humans follow this same pattern. Men compete with other men to mate with women; and women compete with other women to mate with men. Individuals' primary mating rivals are therefore members of their own sex. This competition can take two forms: intrasexual and intersexual. In intrasexual competition, members of the same sex fight against one another directly for mates. In intersexual competition, members of the same sex compete with one another to appeal directly to the preferences of the opposite sex.

Although at the surface, men and women have the same goal – outcompete their same-sex rivals for reproductive opportunities – competition among men and among women relies largely on differing tactics.

Asymmetric Constraints and Benefits

Men and women's mating competition is radically shaped and constrained by the minimum investment they contribute to reproduction. Women, for example, are uniquely responsible for pregnancy, childbirth, and lactation. Therefore, many physiological processes (e.g., umbilical cord development, uterine contractions, milk let down, etc.) must unfold without error for women to reproduce successfully. Because women's bodies are more heavily involved in reproduction than men's, physical injury from violent conflict more strongly jeopardizes women's chances of reproduction. Furthermore, after giving birth, women

are the primary caretakers of dependent children (Hewlett 1992; Hrdy 1999). Women's substantial investment in reproduction (both pre- and postnatally) renders their injury and death costlier for bearing and raising children compared to men's death (Campbell 1999). If a woman were to die from violent conflict, she could no longer care for her dependent children, greatly compromising their chances of surviving. If a man were to die, on the other hand, his female partner could continue caring for the children. Indeed, children are at greater risk of death when their mother dies compared to when their father dies (Hill and Hurtado 1996; Sear et al. 2000). This difference between men and women's investment in reproduction shapes the nature of their mating rivalry. Because the potential risks of physical violence are so substantial for women, women are less likely to use direct physical aggression as a competitive mating tactic than are men (Campbell 1999). Women must find alternate, nonviolent mechanisms of outcompeting their same-sex rivals for the most desirable mates.

Another consequence of men's lower investment in reproduction is that the time it takes a man to reproduce is markedly shorter than the time it takes a woman to reproduce. Men, who are unbridled by pregnancy or lactation, could, in theory, engage in one (or a few) sexual encounter and successfully create a child. At minimum, men must only contribute sperm and the time it takes to copulate, and men are therefore nearly unlimited in the number of offspring they could sire across their reproductive lifespan. Consider one extreme example: genetic analyses reveal that Genghis Khan fathered 0.5% of the entire world's population! From an evolutionary perspective, Genghis Khan won the reproductive jackpot. Although this is an extreme example, it demonstrates that men have a lot to gain from reproductive competition – if they succeed, they can sire many children. Because the potential rewards of reproduction are so substantial for men, taking risks to attract and secure mates is more advantageous for men than women.

Women, on the other hand, are quite limited in the number of children they can produce throughout their reproductive lifespans. Not only is the

timeframe during which women are capable of bearing offspring shorter than men's, women must also endure 9 months of pregnancy for each child (or set of twins, etc.) they produce. Because women are relatively limited in the total number of children they can bear across their lifetimes, women stand less to gain than men from risk-taking or pursuing multiple mates. In theory, women could bear the same number of children with one mate as they could with many mates. Women's mating rivalry therefore is more heavily directed at attracting and securing one (or a few) high-quality mating partner(s) than attracting many mating partners. Men, on the other hand, can produce more children the more women with whom they have sex and therefore stand more to gain from ardently competing for multiple mates.

To successfully attract a mate, men and women must appeal to the preferences of the opposite sex (intersexual competition). To the extent that men and women value different traits in romantic partners, the traits they compete to advertise to potential mates will also differ. The remainder of this entry will outline how mating competition manifests among women and men. Last, it will describe how situational forces (i.e., operational sex ratio) shift the intensity of this competition.

What Are Men Looking for?

Women's ability to bear children across their lifetime is constrained; they are most fecund in their mid-twenties, but their fertility sharply declines thereafter until menopause (Wood 1990). In non-industrial societies, for example, women are, on average, about 35–40 years of age when they give birth to their last child, and the likelihood of having a child past age 46 drops to nearly zero (Hill and Hurtado 1996).

Because women's ability to bear children is so strongly tied to their age, many of the physical traits men find appealing in women are indicative of youth and, consequently, fertility. That is, over the course of human evolution, men who were found sexually attracted to fertile women (and their anatomical features) were more likely to

successfully impregnate those women (because they were fertile) and reproduce. Men who preferred young, fertile women sired more children and transmitted these mate preferences to offspring than did men who were attracted to women who were not fertile. Men who were attracted to prepubescent girls or postmenopausal women would not have successfully reproduced nor passed on their mating preferences to offspring. Over time, then, the human population became filled with men who were sexually attracted to fertile women and the features of women's bodies that indicate fertility.

Men therefore rely heavily on the appearance of women's bodies to ascertain fertility. Although men do not consciously think "she looks fertile" when assessing a woman, men attend to physical appearance when judging a potential mate. Around the world, men more heavily value attractiveness in their long-term mates than do women (Buss 1989). Men's perceptions of female attractiveness are not arbitrary but rather linked to women's underlying health and fertility. Men find bodily cues of women's advancing age, such as gray hair and wrinkles, as sexually unappealing. In sum, because women's bodies are heavily involved in reproduction, men have evolved to be attracted to bodily cues of fertility, and these preferences increase the odds that men will choose mates who are impregnable.

Another consequence of the fact that women are responsible for pregnancy is that women always know they are the biological mothers of the children they birth. That is, women have maternity certainty. Men, on the other hand, never know for certain that the child developing in their female partner's womb is genetically related to them. Men lack paternity certainty, and this uncertainty shapes which traits men find attractive in potential mates. If a man's female partner has likely not had sex with other men, he can be more confident that the child developing in her womb is genetically related to him. Men, therefore, prefer cues of sexual loyalty in their long-term mates. All else equal, men prefer women who are sexually chaste and faithful over women who are sexually promiscuous or unfaithful when selecting which women (and their

children) to invest in. These mating preferences decrease the odds that a man will invest in a child that is genetically unrelated to him, which is called cuckoldry.

Women's Mating Rivalry

Although women are more likely than men to pursue one mate rather than many, the quality of that mate has important consequences for the survival, well-being, and success of women and their children. Throughout history, children have been more likely to die when their mothers were not supported by a male romantic partner (McCalman et al. 2008). Furthermore, when women remain married to their husbands, their children are more likely to later attain social success than if the couple dissolves (Sigle-Rushton et al. 2005).

Polygamy also puts children at risk. In fact, children are more likely to die when their mother shares her husband with another woman compared to when their mother is monogamously married (Omariba and Boyle 2007; Strassmann 1997). When multiple women are polygynously married to one husband, conflict often ensures over access to the husband's material resources and emotional investment (Jankowiak et al. 2005). This conflict may even become violent, harming the fitness of women's children.

If women want to attract a high-quality mate, they must appeal to his mating preferences. Therefore, the domains in which women compete with rivals are shaped by men's mating preferences (i.e., intersexual competition). Because men prefer bodily cues of youth and fertility, women compete with one another to maintain and display physically attractive bodies. To succeed at this competition, women must first size up their competition, assess which are their most threatening rivals, and estimate how they compare relatively. Women consider physically attractive women threatening rivals (Russell et al. 2016). They are most threatened by rivals with feminine faces, large breasts, and a slim waist relative to larger hips (Fink et al. 2014). These physical features indicate youth and fertility and are therefore desired by men (Jasienska et al. 2004). Indeed,

physically attractive women are more successful at securing relationships with wealthy men and luring away rivals' mates, suggesting that women's perceptions of rival threat are accurate (Schmitt 2004; Davies et al. 2010; Sunderani et al. 2013).

To gain a competitive advantage over an attractive rival, women can take one of two approaches: (1) increase their own attractiveness (i.e., intersexual competition) or (2) damage their rival's attractiveness (i.e., intrasexual competition; Campbell 2004).

When women are exposed to an attractive conspecific, they feel less satisfied with their own appearance (Krones et al. 2005). They experience distress when a rival has a relatively more attractive face or body (Buss et al. 2000). This response likely facilitates the first goal: increasing one's own attractiveness. That is, if women feel less satisfied with their appearance, they may be more motivated to augment it. In day-to-day interactions, women report competing to be more physically attractive than their rivals (Cashdan 1998). Women enhance their appearance by applying makeup and donning tight and revealing clothing (Tooke and Camire 1991).

Women also pursue an attractive body shape through diet and exercise to outcompete their mating rivals. In Westernized societies, men prefer slender women, and these women (compared to their heavier counterparts) are more likely to marry men who are taller and wealthier (Fales et al. 2016; Oreffice and Quintana-Domeque 2010). Women report using their bodies and athleticism to compete with other women for male attention (Fisher and Cox 2011). When women are in the presence of attractive rivals who are emphasizing their bodies with revealing clothing, women become less satisfied with their own bodies but particularly if a desirable mate is also present (Ferguson et al. 2011).

Researchers have postulated that mating competition may underlie the more pernicious manifestations of these behaviors (e.g., eating disorders; Abed 1998). Congruent with this contention, women who are prone to eating disorders are not only interpersonally competitive in general but also competitive about mating in particular

than women who are less prone problematic eating (Faer et al. 2005; Schleien and Bardone-Cone 2016). Securing a long-term mate may also ameliorate problematic weight-maintenance behaviors. When women get married, they become more satisfied with their bodies and less motivated to become thin through dieting and purging (Keel et al. 2007; Vogeltanz-Holm et al. 2000). That is, when women have successfully outcompeted their mating rivals in securing a long-term mate, they become less motivated to pursue a thin body, suggesting that some portion of these weight-maintenance behaviors are in pursuit of a mate. However, if women secure a particularly attractive romantic partner and are not attractive themselves, they continue to pursue thinness through dieting (Reynolds and Meltzer 2017). Given that men prefer physically attractive mates, these less attractive women may strive for thinness to preserve the partnership or deter mate poachers.

When exposed to an attractive rival, women not only feel worse about themselves, but they also feel jealousy and anger (Massar and Buunk 2010). These emotions likely facilitate the second mechanism by which women gain a relative advantage: harming rivals' attractiveness. Women are more likely than men to derogate or gossip about their mating competitors' physical appearance (Buss and Dedden 1990; Nevo et al. 1993). Among adolescents, girls critique one another's appearance (Eder and Enke 1991). These comments are effective; men view women as less attractive after they have heard negative comments about their physical appearance (Fisher and Cox 2009). However, attractive women may be especially successful at swaying men's opinions of other women; men were more likely to alter their assessments of a woman if she was derogated by an attractive, compared to less attractive, rival (Fisher and Cox 2009). Given that derogating a woman's appearance can be successful, it is perhaps unsurprising then that women are more likely than men to end a friendship over appearance teasing (Vigil 2007). Women must avoid or socially punish those that might harm men's assessments of their appearance.

Because men could succeed reproductively by pursuing many mating opportunities, men are

relatively open to casual sexual encounters compared to women (Schmitt 2003). Oftentimes, women use casual sex in hopes of securing a long-term committed relationship (Regan and Dreyer 1999). Women must therefore be vigilant toward other women who could lure away romantic partners through sex or by advertising cues of sexual availability. Indeed, women are more likely to have their romantic partners poached by women who are sexually unrestrained than those who are sexually restrained (Schmitt 2004). Women should therefore be sensitive to features that signal sexual openness in their same-sex rivals.

Women are quite hostile toward other women who are sexually promiscuous (Baumeister and Twenge 2002). Women believe that other women judge them more harshly than do men for their sexual behaviors (Milhausen and Herold 1999). Women who embrace their sexuality report that other women often judged, accused, and rejected them (Blumberg 2003). As one woman described, "They see me as sluttie. . . the way they look you up and down. The way they size you up when you walk into a room. The way they watch you when there's a male in the room. And they get upset, or they tend to tense up" (p. 152; Blumberg 2003). Indeed, women are unwilling to befriend sexually promiscuous women (Bleske and Shackelford 2001). Women who are more sexually experienced are more likely to be teased, demeaned, and excluded and have rumors spread about them than their less sexual peers (Gallup et al. 2009). Even indirectly suggesting one's sexual openness is enough to evoke the scorn from other women. In a lab study, when a female confederate dressed provocatively, other women responded with harsh glares, rude comments, and lower willingness to befriend her or introduce her to their boyfriends (Vaillancourt and Sharma 2011).

Although men find women who are sexually open immediately appealing, men are cautious to engage in long-term committed romantic relationships with these women (Oliver and Sedikides 1992). As mentioned, men do not want to mistakenly invest in another man's baby, and so they avoid women who might commit sexual infidelity.

Indeed, men are highly distressed by the thought of their mate's sexual infidelity (Buss et al. 1999). Suspected infidelity is one of the best predictors of divorce and spousal abuse (Betzig 1989; Daly and Wilson 1988).

Because men care about the likelihood their female partner will commit infidelity, questioning a woman's likelihood of staying sexually faithful to a man is an effective way of harming her desirability as a long-term mate (Schmitt and Buss 1996). That is, women can harm their rivals' long-term mating appeal by drawing attention to rivals' sexual openness. One way women accomplish this goal is by transmitting information about their rivals' sexual promiscuity. Compared to men, women are more interested in gossip about their same-sex rivals and more likely to share it with their same-sex friends (McAndrew et al. 2007). Across cultures, women have a higher tendency to gossip than do men (Nevo et al. 1993). Moreover, women are especially interested in information about other women's sexual promiscuity and infidelity, suggesting that this information is valuable in reputational competition (McAndrew and Milenkovic 2002).

One investigation straightforwardly tested the prediction that women would use social information strategically against their same-sex rivals (Reynolds et al. 2017b). Across five studies, women were more likely to transmit reputation-harming information about rivals who were more, compared to less, threatening mating rivals. Women were more likely to disclose that another woman was sexually promiscuous, had a sexually transmitted disease, and cheated on her last romantic partner when the woman was attractive (vs. unattractive), flirtatious with their mates, or dressed provocatively (vs. conservatively). These findings suggest that women compete with one another through strategically influencing social reputations (Hess 2006, 2017).

Although women strategically harm the reputations of women who are threatening mating rivals, women may not necessarily realize consciously what they are doing. Instead, women may simply believe they are concerned about the targets of their gossip. Indeed, women were more likely to disclose that another woman had engaged

in drunken sexual behavior when she was dressed provocatively rather than conservatively, but many of the gossipers phrased their disclosure as concern (e.g., “I am worried about her”; Reynolds et al. 2017a).

Appearing concerned when gossiping may be a competitive mating tactic. Women who believe they are concerned about their gossip targets might phrase their gossip nicely rather than maliciously, which may protect them against the social costs of engaging in overt gossip. For example, people generally dislike gossip, but especially when the gossip is negative, self-interested, or competitively motivated (Beersma and Van Kleef 2012; Turner et al. 2003). Women who found ways to disguise their gossip should have a social advantage over women who gossip in an overtly malicious manner. Indeed, compared to men, women report that their social conversations were less intended to harm their targets and were more strongly motivated by concern (Reynolds et al. 2017a). Furthermore, gossipers are perceived as more likeable, trustworthy, and desirable as romantic partners when they frame their gossip as concern rather than malice (Reynolds et al. 2017a). Therefore, women may believe that they are seeking to help their targets when they gossip, not realizing consciously that they are nonetheless transmitting their target’s social information, and effectively harming their targets’ reputations. Laura Tracy (1991) found support for these misbeliefs when she interviewed women about female-female competition: many women reported that other women were competing with them, but they were not competing themselves.

Men’s Mating Rivalry

Although men do not make similarly large physiological investments toward reproduction as women, men can nonetheless provide in ways that help children’s outcomes. Men’s provision of time and resources enhances the odds their offspring will not only survive but also thrive in society (Geary 2000). Women mated to such men had higher reproductive success than women who mated with men who did not invest in them and

their children. Over time then, the population became filled with women who were attracted to cues of investment and resources in their mates. In order to attract the best mates, men compete with one another to signal these traits to women.

To signal resources to mates, however, men must first acquire them. A substantial component of men’s mating competition involves competing with other men to acquire resources. Men compete against other in-group men for status, which predicts men’s access to the group’s resources. However, across human history, men have also competed *as groups* against other groups of men for access to territories, resources, and mates (Geary 1998). Unlike women’s mating competition, men’s mating competition involves both within-group and between-group components.

Because men competed in groups (e.g., armies), the traits that predict within-group status among men are typically those that aid in between-group competitions. Throughout history, successful male coalitions gained access to the defeated group’s territory, resources, and women. Men who comprised such formidable groups therefore succeeded not only on the battlefield but also reproductively (Carvajal-Carmona et al. 2000). Therefore, the success of the group influenced the reproductive success of the men who comprised it. Men’s intragroup competition therefore rendered their mating competition less zero-sum than women’s.

Likewise, the traits of the men who comprised the group influenced the success of the group. Men who are physically strong, dominant, aggressive, courageous, and loyal to the group increased the odds their groups succeeded in combat. Men have therefore evolved to prefer men who possess these traits as coalition partners and defer to them in exchange for their contribution to the coalition (Henrich and Gil-White 2001; Winegard et al. 2014). Indeed, modern men prefer other men who are dominant, strong, and courageous as partners in competitions. This preference may explain some portion of men’s antigay bias. Indeed, men expect gay men to be lacking in these traditionally masculine traits (e.g., toughness, strength). However, when masculinity and sexual orientation are directly manipulated, men

prefer a partner who is homosexual and masculine over one who is heterosexual and feminine (Winegard et al. 2016). This pattern suggests that men's antigay bias is largely an anti-effeminate bias and likely stemmed from their evolutionary history of coalitionary competition.

To assess the traits of their potential coalition partners, men vet one another using tests of strength, courage, loyalty, and pain tolerance (Sosis and Alcorta 2003). Men who can withstand such challenges are rewarded with respect and deference from other men. This deference creates a hierarchy of dominance, in which the most dominant (and group-benefitting) men are at the top and less dominant men are in subordinate positions. It is within the interests of the subordinate men to defer to the dominant for a few reasons. First, the dominant men are usually more physically formidable and could severely injure or kill their weaker counterparts. Second, dominant men promote the group's success in intertribal warfare. If the group succeeds in these battles, then even the subordinates will benefit from the group's victory, attaining access to the losing group's resources and women. Indeed, genetic analyses reveal that across history, men from successful groups mated with losing groups' women, thereby propagating their genes (Carvajal-Carmona et al. 2000).

This history of warfare and aggression has shaped not only men's psychological but also morphological traits. Compared to women, men are 90% stronger in their upper bodies and 65% in their lower bodies (Lassek and Gaulin 2009). Because of these large differences in musculature, the average man is stronger than 99.9% of women (Lassek and Gaulin 2009). Muscularity enhances perceptions of men's dominance and is sexually attractive to women (Frederick and Haselton 2007). Indeed, muscular men are more likely to be chosen as women's sexual partners than their leaner counterparts (Frederick and Haselton 2007). However, researchers have argued that throughout most of human history, women were not the choosers of their long-term mates. Instead, families arranged advantageous unions (Apostolou 2007), or dominant men used physical force to exclude competitors from their mates (Puts 2010).

Given that muscularity predicts other men's assessments of dominance and deference and women's sexual attraction, men are quite motivated to pursue muscular physiques. When men are unhappy with their bodies, it is usually because they desire to be more muscular (Bergeron and Tylka 2007). Compared to women, men are more compelled to augment their muscularity (Smolak and Murnen 2008), and many men use body building supplements, such as anabolic steroids, to do so (Olivardia et al. 2004).

In modern times, men may use sports to assess and signal one another's strength and athletic prowess. Compared to women, men feel more competitive with their peers over athletic ability (Cashdan 1998) and use physical activity and sports as forms of competition (Apostolou 2015; Kilpatrick et al. 2005). Along with providing a signaling arena for physical prowess, modern-day sports likely appeal to men's interest in coalitional activities. Indeed, men are more likely than women to participate in organized sports but particularly team sports (Deaner et al. 2012).

Men who climb to the top of dominance hierarchies earn status within their groups. This high status grants them priority access to the group's resources and women. Indeed, around the world, women are attracted to men who have high status and access to resources (Buss 1989). Among the Yanomami tribe, for example, men who have killed more enemy males in intergroup conflict have more wives than men who have not contributed as substantially to the group's success (Chagnon 1988).

Another way that men earn status within a group is through hunting. Throughout human history, hunters were primarily men. Men who were successful hunters provided more calorically dense meat for their social groups. These high-contributing men therefore became highly valuable within the social community. Indeed, in foraging societies, men's reputations for hunting ability predict their social standing relative to other men in the group (Kelly 1995; Wiessner 1996). This high social status translates into more mating opportunities. In non-Westernized

societies, for example, men who are better hunters have more sexual partners, marry younger and more fertile women, and ultimately father more children than men who are not as skilled hunters (Blurton Jones et al. 1997; Kaplan and Hill 1985; Smith and Bleige Bird 2000). It is rational for women to be attracted to these highly skilled hunters; although meat is often shared with the group, families of the hunter get a larger share (Wood 2006). Hunting has therefore been a domain of intrasexual competition for men, with the winners attracting more mates and fathering more offspring.

Local Conditions Influence the Intensity of Mating Rivalry

Mating rivalry is not monolithic among the sexes. Instead, the immediate social landscape shapes the degree to which men and women must compete for mates. One factor that dictates the intensity of mating competition is the operational sex ratio – the ratio of fertilizable females to sexually active males within a population at a given time (Emlen and Oring 1977). The sex ratio dictates the number of one's rivals relative to the number of one's potential mates. As the proportion of women relative to men increases, so too does the level of female competition for mates. Conversely, male mating competition increases when there are proportionately more men in the population. When the sex ratio is unfavorable (proportionately more rivals), both sexes increase their intersexual and intrasexual competitiveness.

To increase their intersexual appeal, or to become more desirable to the opposite sex, men and women tend to shift their mating strategies to that of the opposite sex (Moss and Maner 2016). As previously described, on average, women tend to be more selective about their mating partners than men because women incur substantial physiological burdens from reproduction (e.g., pregnancy, lactation). Men, on the other hand, are relatively more open to casual sex because they can substantially increase their reproductive success by impregnating more fertile women.

Although these are the typical strategies of the sexes, these strategies shift to those of the opposite sex when the operational sex ratio is disadvantageous.

When men are more prevalent in the population, men become more willing to invest in romantic partners and less open to casual sex (Moss and Maner 2016). Men's mating strategies therefore more closely match those typical of women. Indeed, historical records indicate that divorce rates are lower and rates of paternal investment increase during times when men are the more prevalent sex (Pedersen 1991; Pollet and Nettle 2008). Furthermore, when men are disfavored, they become more willing to take financial risks to acquire resources (i.e., incur more debt) and are more willing to buy potential mates lavish gifts (Griskevicius et al. 2012). Thus, men must appeal to women's mating preferences (i.e., commitment, resource investment) when they are the prevailing sex. Conversely, when women are more abundant, sex norms become more liberal, divorce rates increase, births out of wedlock increase, paternal investment decreases, and the proportion of single mothers increases (Guttentag and Secord 1983). That is, when women are more prevalent, they can no longer afford to demand high levels of commitment or investment from their male partners and instead pursue a more unrestricted sexual strategy (Moss and Maner 2016).

When the sex ratio is unfavorable, men and women also increase their intrasexual competitiveness (Moss and Maner 2016). That is, they compete or aggress directly against members of their own sex. For men, this increased aggression manifests in the form of increased violence. Indeed, historical analyses indicate that periods when men were more abundant (relative to women) are characterized by more social unrest, violence, and expansionistic military directives (Hudson and Den Boer 2002, 2004). Women, on the other hand, are more likely to turn to mate poaching when they are the more abundant sex. Across the world, women are more likely to lure away other women's mates when there is an overabundance of women (Schmitt 2004).

Conclusion

Although both men and women must compete with their same-sex rivals for desirable mates, this competition manifests quite differently among each sex. Women, who are the physiological vessels of reproduction (i.e., their bodies house and nourish developing offspring), compete to advertise their physical attractiveness (and hence fertility) and sexual fidelity to potential partners. They also derogate these traits in one another. Men, who can provide resources and protection to their female partners and offspring, compete to acquire status (and consequently resources) through hunting and intergroup competitions. Because men often competed in coalitions, which led to increased mating opportunities, their same-sex mating competition may be less zero-sum than women's. Women, on the other hand, were forced to compete among one another for the limited high-status men within their social groups. For men and women alike, the intensity of this mating competition is influenced by immediate social conditions, such as the operational sex ratio.

Definition

A set of evolutionary adaptations which evolved to maximize the reproductive success of individuals.

Introduction

A mating strategy can be defined as a set of behavioral and cognitive adaptations which drive reproductive efforts of individuals. The ultimate aim of mating strategies is to maximize reproductive success. These strategies also affect individual investment in mating and parenting (Buss and Schmitt 1993; Gangestad and Simpson 2000). Each consists of specific mating tactics in the form of individual behavior (Gangestad and Simpson 2000). Importantly, mating strategies and tactics are often nonconscious, and their activation strongly depends on specific contexts and circumstances, such as the sex ratio in the mating pool, mate value of individuals concerned, or

cultural norms (Buss and Schmitt 1993). Evolutionary psychologists agree that humans evolved more than one “ideal” mating strategy, which implies that there is no single mating strategy that would be optimal for every individual in any situation. Moreover, human mating strategies are variable and flexible, so that individuals can mix and match them (Buss and Schmitt 2016).

There are two main theories of human mating strategies. The first is *sexual strategies theory* (Buss and Schmitt 1993, 2016). It works mainly with intersexual differences which result from the asymmetry of parental investment. The second is *strategic pluralism theory* (Gangestad and Simpson 2000), which highlights intrasexual variation in mating behavior rooted in individual differences.

Sexual Strategies Theory

According to Trivers’ theory of parental investment and sexual selection (Trivers 1972), men and women face different adaptive problems in mating and parenting, and that leads to different mating strategies and tactics. In mammals generally, investment into reproduction is higher in females than in males: females invest at the very least in pregnancy, childbirth, and lactation, whereas male contribution can be minimal, just the sexual act. This disproportion in reproductive biology led to the development of sex-specific mating strategies. Most generally, we can distinguish between a long-term mating strategy characterized by pair bonding, biparental investment, and relationship commitment and a short-term mating strategy marked by absence of commitment and exclusivity.

As noted above, the sexual strategies theory emphasizes sex differences in mating strategies. Due to high investment in reproduction, women are said to profit more from long-term strategies, which should guarantee resources needed to raise children. Men, on the other hand, are more likely to prefer short-term mating strategy and tactics because a higher number of sexual partners can increase their reproductive success. There is a large body of cross-cultural research which supports these predictions (Buss 1989; Buss and

Schmitt 2016). Furthermore, the sexual strategies theory indicates under what circumstances it is advantageous for both sexes to mix the short- and long-term strategy (Buss and Schmitt 1993, 2016). In fact, short-term strategies can lead to long-term relationships and vice versa (for a review of advantages and disadvantages of short- and long-term mating strategy for each sex, see Buss and Schmitt 2016).

In general, sexual strategies theory posits that both women and men have long- and short-term strategies in their repertoire. This theory has the ambition of using rather straightforward distinctions to produce a complex image of mating. Mating, however, can be influenced by other kinds of factors, such as individual differences, temporal context, or social factors (Buss and Schmitt 2016). By focusing on intersexual differences in mating strategies, sexual strategies theory seems ill-equipped to account for intrasexual variation, which is vast and of undoubted importance.

Strategic Pluralism Theory

The strategic pluralism theory, formulated by Gangestad and Simpson (2000), focuses on differences in mating strategies within each sex rather than between the sexes. It describes how individual characteristics in conjunction with environmental factors can lead to flexibility and pluralism of mating strategies. In general, the strategic pluralism theory views mating strategies through the prism of cost-benefit analysis. It states that individuals adopt a mating strategy based on how “advantageous” it is under given circumstances. Strategic pluralism theory works extensively with *good genes* and *good provider* theories. Depending on circumstances, women make a trade-off between men’s genetic quality and their ability and willingness to support them and their offspring. It is assumed that few individuals meet both of these criteria equally well. Factors which affect the particular form of compromise a woman makes with respect to choosing a partner who has good genes or one who promises to be a good provider fall into three broad categories: first of all, woman’s own characteristics, such as health, age, physical attractiveness, or mate value in the mating market;

second, her access to resources, meaning that women who have sufficient resources either of their own or through their families may be independent of additional resources from a potential partner; and finally, environmental factors in the sense of life in an environment with stable and sufficient resources, presence of various pathogens, and the like. If a woman has sufficient resources and can find a better short-term than long-term partner, it may be more advantageous for her to engage in a short-term relationship, thus “exchanging” man’s parental investment for good genes. If, on the other hand, a woman lives in an environment where biparental care is crucial for children’s survival, it is likely she will favor men with better parental skills. In short, such conditions promote women’s long-term strategy. In human evolutionary history, women have been exposed to a large variety of environments. This led to the development of the range of mating strategies still in use today.

Since women are, generally speaking, more choosy sex, men’s mating strategies are to some extent limited by women’s choices. Short-term strategy may be advantageous for men who display high genetic quality, for instance, by low fluctuating asymmetry, high masculinity, or dominant behavior (Durante et al. 2016; Gangestad and Simpson 2000). In general, men could be expected to pursue a short-term strategy which can increase their reproductive success by mating with more women. This strategy is not, however, universally advantageous. In particular, it does not increase reproductive success of men who do not meet the demands placed on short-term male partners. In fact, according to the strategic pluralism theory, long-term strategy is the most advantageous strategy for most men, although a small proportion of men can achieve higher reproductive success via the short-term strategy.

All in all, both men and women make compromises between mating and parenting and that affects their mating strategies. Both sexes can therefore pursue both types of strategies or mix and match them according to what is beneficial given their circumstances and surrounding conditions (Durante et al. 2016; Gangestad and Simpson 2000). Nevertheless, strategic pluralism theory does not explain how other important

variables, such as self-perceived mate value and sociosexual orientation of attachment style, affect mate choice and how these factors help maintain romantic relationships.

Conclusion

Evolutionary theories on human mating are meaningfully anchored in men’s and women’s different biological roles reproduction. According to Trivers’ theory of asymmetric investment, minimal obligatory investment in reproduction is higher in women than in men (Trivers 1972). Nevertheless, biparental care is the dominant pattern in human societies, and paternal investment of both sexes is relatively high during offspring’s childhood. Both sexes therefore invest in their children and that has a significant impact on their mating strategies and preferences.

Mating strategies are a set of evolutionary adaptations which promote the reproductive success of individuals. In other words, their aim is to maximize the number of children and grandchildren by coupling with the best possible partner. In humans, the range of mating strategies is considerable and varies from exclusively short-term to exclusively long-term strategies. Analogically, people form a wide range of sexual relationships, ranging from commitment-free short-term relationships, such as casual hookups or one-night stands, to committed long-term relationships, such as marriage. Importantly, short-term strategies can lead to long-term relationships and vice versa. Mating strategies include a range of possible tactics which are mostly unconsciously used to attract – and in some cases establish a relationship with – the desired partner. Which strategies are actually employed depend not only on the sex but also on the individual (e.g., his or her age, personality, mate value, sociosexual orientation, life history, and attachment style), on the environment (pathogen prevalence, predictability of resource availability, and ecological stability), and on cultural factors (Marzoli et al. 2018). High levels of variation in mating strategies are therefore found not only between but also within the sexes. Moreover, mating strategies can be influenced by

individuals' families: for instance, a woman who can rely on the support of her family can focus on potential partner's socioeconomic status less than a woman for whom such support is not available. Moreover, not all relationships, and not all sexual activities, lead to reproduction. Romantic relationships can promote the formation of social coalitions (Lancaster 1975); sex can provide safety from physical harm (Hrdy 1981) or be exchanged for food or other items (Hill 1982). Nevertheless, all these factors have the potential to promote reproduction success. All these factors, not only sex, should be therefore considered in further research on human mating strategies.

Evolutionary stable strategies

Definition

Mating strategy equilibria refers to alternative mating phenotypes being maintained in a population in an evolutionarily stable equilibrium.

Introduction

In terms of evolutionary game theory, a “strategy” is a genetically determined decision rule that regulates how different behavioral phenotypes (tactics) are manifested (Gross 1996).

Evolutionary strategies are stable; if after reaching a critical proportion within a population, no other alternate strategy can do better (Maynard-Smith 1982). Behavioral strategies can include multiple distinct phenotypes (tactics) that are maintained at an evolutionary stable equilibrium. This is often seen with “alternative mating tactics” in which individuals adopt different behavioral phenotypes to access mates. This section will discuss how alternative mating tactics can evolve and be maintained within populations in a stable equilibrium.

Alternative Strategies

An alternative mating strategy is a decision rule that is governed by inherited genetic polymorphisms leading to distinct behavioral phenotypes. These genetically distinct phenotypes can exist in a population in a stable equilibrium through frequency dependent selection (Maynard-Smith 1982; Gross 1996). Assume a population where the frequency of a strategy X is f , the frequency of a strategy Y is $1-f$, and at least one of these strategies is under negative frequency dependent selection (Fig. 1). The frequency at which the fitness functions of these strategies intersect is the evolutionary stable state frequency (ESS f^*). At this frequency, the average fitness of X and Y are equal, and they are stable within the population (Gross 1996). There are a few examples of alternative mating strategies in natural populations, although they appear rare. In the ruff, *Philomachus pugnax*, alternative mating strategies consist of genetically determined independent (territorial), satellite, and female-mimicking

Mating Strategy Equilibria, Fig. 1 Fitness of strategy X and Y relative to the frequency of Y in the population. The average fitness of X and Y are equal where the fitness functions intersect. The frequency at which the fitness functions cross is the evolutionary stable state frequency (ESS f^*) (Gross 1996)

(faeder) males (Lank et al. 1995). The genetic distinction between these morphs appears to be an inverted region of a chromosome consisting of around 4.5 Mb. Independent males are homozygous for the ancestral state in this region, while satellite and faeder males are heterozygous for the inverted state. Sequences for satellite and faeder males are significantly divergent within an internal region of this inverted section (Lamichhaney et al. 2016). While ruffs are often given as an example of a species with alternative mating strategies due to these genetic polymorphisms, there is still relatively little quantitative data assessing whether the male morphs are under frequency dependent selection or have equal average fitness values. These data will be important to fully establish whether these phenotypes are true alternative mating strategies.

Mixed Strategy

In a mixed strategy, the decision rule is that individuals will adopt tactic X with a probability of p and tactic Y with a probability of $1-p$ (Maynard-Smith 1982). There is no genetic polymorphism

driving these differences, and the likelihood that an individual adopts either tactic is purely probabilistic. As such, there is a stochastic aspect regarding which behavior is adopted. Similar to alternative strategies, mixed strategies can be maintained at a stable equilibrium with equal average fitnesses through frequency dependent selection (Gross 1996). Presently, there is little empirical evidence that mixed strategies actually occur in natural populations. In order for this to happen, it would have to be shown that the tactics have equal average fitness, they are under frequency dependent selection, they are genetically monomorphic, and that the likelihood of adopting one tactic over another is purely probabilistic (Gross 1996).

Conditional Strategies

Conditional strategies involve a decision rule where individuals adopt a behavior based upon their condition or status. The behavior adopted should provide the individual the highest fitness given their specific condition. The difference between this and the mixed strategy is that under the mixed strategy scenario, a behavior is assigned randomly with a given probability from a set of possible actions (Maynard-Smith 1982), while for a conditional strategy an action is performed when a specific condition is met (Dawkins 1980). The majority of alternative mating tactics are likely to be conditional strategies. For example, in dimorphic dung beetles, *Onthophagus acuminatus*, males that reach a certain size develop large horns and adopt a fighting tactic to access females, while smaller individuals either developed reduced or no horns and use a sneaker tactic. Both body size and horn length is dependent on larval food intake, and these traits can be experimentally manipulated by altering food quality (Emlen 1994).

Conditional strategies were initially described to be genetically monomorphic (Dawkins 1980) and Gross (1996) proposed that this type of strategy could evolve through “status-dependent selection.” In the status-dependent selection (SDS) model, individuals will vary in their state due to a combination of environmental, genetic, and developmental factors. These factors come

together to influence the “status” of an individual relative to others in the population, which then influences their mating success and fitness. In this case, the average fitnesses of the different tactics do not have to be equal to be at an evolutionary stable equilibrium. Rather, there is an intermediate status, s^* , at which the fitness functions of the two tactics are equal, and this is termed the evolutionary stable strategy switchpoint (ESS s^*) (Fig. 2). Individuals below s^* should adopt tactic Y, while those above s^* should adopt tactic X. The different phenotypes would not have to be maintained by frequency-dependent selection, but shifts in the ESS s^* can alter the frequency of the tactics in the population (Gross 1996; Tomkins and Hazel 2007).

One critique of Gross’s SDS model is that these tactics are described as genetically monomorphic. However, as pointed out by Tomkins and Hazel (2007), this was mainly to distinguish conditional strategies from alternative strategies in game theory models. Without some heritable variation in the switchpoint, evolution cannot act to maintain the switchpoint at an evolutionary stable state. Conditional strategies are

Mating Strategy Equilibria, Fig. 2 The fitness of phenotypes relative to individual status. The fitness of X and Y are equal where the fitness functions intersect. The status at which they intersect is the intermediate status, s^* . Individuals below s^* should adopt tactic Y, while individuals above s^* should adopt tactic X (Gross 1996)

Mating Strategy Equilibria,

Fig. 3 Selection differential relative to the population mean switchpoint. When the selection differential is zero, the mean switchpoint is at a stable equilibrium (Tomkins and Hazel 2007)

more likely regulated by a combination of genetic and environmental (GxE) factors (Hazel et al. 1990; Hazel et al. 2004; Neff and Svensson 2013). Individuals will adopt one tactic or the other depending on whether an environmental regulated cue (such as size) surpasses a threshold value that is individually variable and governed by additive genetic effects. Quantitative genetic models, such as the evolutionary threshold (ET) model (Hazel et al. 1990; Hazel et al. 2004; Tomkins and Hazel 2007), take into account how variation in switchpoint among individuals, the distribution of environmental regulated cues, and the fitness functions for each tactic drive changes in the mean population switchpoint from one generation to the next. Changes in the mean population switchpoint between generations is termed the switchpoint selection differential. In these models, the mean switchpoint is at equilibrium when the selection differential is zero (Fig. 3), and this can occur even when the average fitnesses of the different tactics are not equal (Tomkins and Hazel 2007).

Conclusion

Three strategies have been used to explain how alternative reproductive phenotypes are produced and maintained in an evolutionary stable equilibrium. These include alternative strategies, mixed strategies, and conditional strategies. Both the alternative strategy and mixed strategy models

require that alternative phenotypes be under frequency dependent selection and have equal average fitness values. However, conditional strategies can evolve without frequency dependent selection or equal fitness values among the tactics. While there are some examples of alternative mating strategies, many alternative mating tactics likely fall under conditional strategies.

Definition

The ratio of reproductive variance in men to reproductive variance in women.

Introduction

Most of us take for granted that *Homo sapiens* is monogamous. That hasn't been, is not, and probably never will be the case. Men – like other males – invest little in each of their gametes,

and, like other male mammals, they invest nothing in gestation and lactation. Women invest more. As Charles Darwin, who wrote the book on *Sexual Selection* and attached it to his work on the *Descent of Man*, pointed out: “The female has to expend much organic matter in the formation of her ova, whereas the male expends much force in fierce contests with his rivals, in wandering about in search of the female, in exerting his voice, pouring out odoriferous secretions, &c” (Darwin 1874, p. 224; Trivers 1972).

Over the course of its roughly 200,000-year evolution, *Homo sapiens* has been a polygynous species. Occasionally, a polyandrous (“many men”) woman mates with more than one man – either one after another or at the same time. But more often, a polygynous (“many women”) man mates with more than one woman – either one after another or at the same time. Overall, the reproductive variance of human males has exceeded the reproductive variance of human females: The effective breeding population of women has been greater than the effective breeding population of men.

At the beginning, as at the end, of human time, most people were breeders. Demographic, ethnographic, archaeological, and genetic evidence suggest that in many of the societies of prehistory, reproductive variance for both men and women was low. Among foragers past and present, the most reproductively successful parents probably counted their children in single digits.

But in most of the societies of history, male reproductive variance was high. From the first genetic histories pieced together in the twenty-first century to the first written histories of around 5,000 years ago, the effective breeding population of human males has been extraordinarily small. Heads of the first civilizations were remembered as the fathers of hundreds of children, by thousands, or tens of thousands, or a hundred thousand women. Most lived in enormous palaces or saved places for large numbers of sons in their family tombs. And some left evidence of their reproductive prowess on widespread Y chromosomes.

Low Polygyny

For most of the hunter-gatherer groups for which we have demographic evidence, both ranges and variances in reproductive success tend to hover in, or around, single digits. At the high end, in the forests of Paraguay, Aché men report an average of 6.4 live births, with a variance of 15.05, and at the low end, in the Kalahari, !Kung men report fathering 5.14 children on average, with a variance of just 8.6. Ranges are similarly small. The most reproductively successful foragers we know of were the fathers of from 12 to 16 children. The figures are similar for forager women. At the low end, Aché women report an average of 7.84 live births, with a variance of just 3.57, and at the high end, Hadza women report 4.58 children on average, with a variance of 7.7. Again, all of the ranges are small. The most reproductively successful forager mothers produced 9–12 children. In every one of these forager cultures, the most reproductively successful father had more children than the most reproductively successful mother. And reproductive variances for women were always lower. The highest variance reported for women (7.7 for the Hadza) is lower than the lowest variance reported for men (8.6 for the !Kung). But overall, the sex differences for hunter-gatherers are consistently small (Table 1 and Fig. 1; see Murdock 1984 for ethnographic sources). They might have been larger in the past.

Our best demographic data on living hunter-gatherers were collected in bad habitats. These days, most foragers live on the margins, from the deserts of southern Africa to the Arctic tundra. In the Pleistocene, their environments would have been better. And foragers in better habitats – along coastal strips and inland waterways, where climates are consistent and resources abound year-round – tend to be more sedentary than other foragers. From the Pacific Rim in the Americas to the Pacific Rim in Japan, foragers in consistently rich habitats were more likely to call themselves “big men” and to raise families by more than one woman.

Notes kept by early European explorers corroborate that. When James Cook showed up on the coast of Vancouver in his ship, *Resolution*, in 1778, he was hoping to find a way through to Hudson’s Bay. He found a few Nuu-chah-nulth Indians “hallooming” from their canoes, instead. Most were friendly, if not, as far as the captain was concerned, pretty. As he scribbled in his *Resolution* journal on 26 April, he thought the women were flat faced, crooked legged, and short – “very much so and hardly one, even of the younger sort, had the least pretensions to being called beauties.” Native men thought different. If he’d stuck around, Cook would have found that Nuu-chah-nulth men with high rank liked to collect women like that, especially chiefs. In summer and winter settlements all along the salmon-rich Northwest Coast – from the Tlingit of the Alaska Panhandle to the Haida of the Haida Gwaii, or the Queen Charlotte Islands, off the coast of British Columbia, to the Nuu-chah-nulth of Vancouver, to the Columbia River Chinook – chiefs had sexual access to on the order of ten wives and to dozens of war captives in their cedar-plank houses, and they probably counted their children in double digits (Cook, *Journal*, 4/26/1778).

At the other end of the Americas, half a century later, Charles Darwin sailed into Tierra del Fuego aboard *HMS Beagle* and spent time with the natives. “These were the most abject and miserable creatures I anywhere beheld,” he wrote. He wondered, in his *Beagle* journal, what had made them leave their fine habitats further north and travel down the backbone of the continent, where they lived in wigwams that resembled haycocks – the work of an hour, used for no more than a few days – and slept curled up in the nude on cold ground. They subsisted mostly on shellfish, in groups with no government or chief. But they managed to be polygynous. After a Fuegian woman traded a good supper for scarlet cloth, Darwin wrote: “Her husband, who enjoyed the very universal privilege in this country of possessing two wives, evidently became jealous of all the attention paid to his young wife, and, after a consultation with his naked beauties, was

Mating Systems, Fig. 1 Ranges in reproductive success for men and women in hunter-gatherer (*top*), herder-gardener (*center*), and full-time farmer (*bottom*) populations. *White bars* for women and *black bars* for men (After Betzig 2012)

paddled away by them” (Darwin, *Journal*, 2/25/1833, 3/5/1834).

Archaeologists have uncovered perforated snail shell ornaments and ostrich eggshell beads, ocher and hematite pencils, points and blades, bone tools, and grinding stones from Africa that date to around 100,000 to 200,000 years ago or before. Portable artifacts like those would have been carried in limited amounts, by foragers who lacked significant differences in status, wealth, or reproductive success.

On the other hand, archaeologists have unearthed some evidence of sedentism for almost as long as we’ve been human. From Africa, post-holes for wall supports and deliberately constructed stone hearths from the Middle Stone Age suggest a settled life. And there are burials, with associated grave goods, from around 100,000 years ago in the Levant (Mellars et al. 2007). Sedentary or semisedentary men in

the past, like sedentary or semisedentary men in the present, probably had higher reproductive variance.

Genetic evidence backs that up: Over the long stretch of prehistory, people probably practiced polygyny. Elevated levels of diversity on the human X chromosome, and extremely low diversity on the human Y chromosome, suggest a consistent difference between the sexes in reproductive variance. The effective breeding population of women is likely to have been consistently larger than the effective breeding population of men.

Across contemporary populations including the Khoisan, a group of people in southern Africa that includes the !Kung, genetic estimates of the breeding sex ratio are consistently biased in favor of women. That is, fewer males than females have contributed genes to descendant generations. A larger fraction of the female population has

reproduced; a larger fraction of the male population has not. *H. sapiens* has been polygynous (Hammer et al. 2008; Lippold et al. 2014).

Moderate Polygyny

Both ranges and variances in reproductive success are higher for semisedentary gardeners and herders than for more mobile hunters and gatherers, and they tend to reach double digits for men. Successful, semisedentary fathers in this sample all number their children in double digits, from 12 (Pimbwe) to 22 (Tsimane), to 23 (Xavante), to 30 (Yomut), to 43 (Yanomamö), to 80 (Kipsigis). But ranges and variances for semisedentary women remain in, or around, single digits. The most successful mothers in this sample produced from 8 (Xavante) to 18 (Yomut) daughters and sons. Reproductive variances for herder-gardener men are consistently greater than for herder-gardener women; sometimes, they're more than ten times as high (Table 1 and Fig. 1).

Gardeners put down roots: They are almost always more settled than hunters and gatherers. Some live in the middle of continents, in predictable climates; many inhabit islands or live along coasts. Gardeners in better habitats, like foragers in better habitats, tend to form more permanent groups, and their "headmen" or "chiefs" tend to be more polygynous (see Murdock 1984 for ethnographic sources).

That was often the case on first contact with islanders across the Atlantic and Pacific. After the Genoese sailor, Cristoforo Colombo, made landfall in the Bahamas in October of 1492, he wrote home to Ferdinand and Isabella of Spain: "I assure Your Highnesses that it seems to me that under the sun there can be no better lands." Columbus would make four trips across the Atlantic, with stops in the Bahamas; at Cuba, Jamaica, Hispaniola, and Puerto Rico; in the Lesser Antilles; on the north coast of South America at the mouth of the Orinoco River, and on the Central American coasts of Honduras, Nicaragua, Costa Rica, and Panama. He'd name one island the Fat Virgin, or *Virgin Gorda*, and he'd call an archipelago *Santa*

Ursula y las Once Mil Virgenes, for St Ursula and her 11,000 uncorrupted young women. Wherever he looked there was plenty of water, with cultivated plains where cassava was grown; the men were all handsome and well formed, and there were plenty of fine-figured women. Most men contented themselves with just one of those women, but dozens might belong to a single *caçique*, or chief (Columbus, *Diario*, 11/27/1492).

At the other end of the earth, there was a *tu'i* in Fiji and a *tu'i* in Tonga, an *ali'i* in Samoa, and an *ali'i* in Hawaii, and in the Trobriand Islands off the coast of New Guinea, there were more polygynous chiefs. Centuries after Columbus, and more than a 100 years after the French ship, *Espérance*, first made contact with the indiginies in the late eighteenth century, the Polish anthropologist, Bronislaw Malinowski, stopped by and took notes. From each of their subject villages, a Trobriand chief took a wife, and their families, his in-laws, supplied him with produce. Strong chiefs like Omarakana, who knew Malinowski, married as many as 40 times. "Even now, when his wives number only 16, he has enormous storehouses, and they are full to the roof with yams" (Malinowski 1922, p. 64).

After we left Africa, inequality increased. In eastern Eurasia, in over a thousand Upper Paleolithic archaeological sites, bordered by the Ural Mountains to the east and the Carpathian Mountains to the west, men, women, and children were buried with hoards of Arctic fox bone beads, bracelets, pins, pendants, and Venus figurines. Cave paintings at Maros in Indonesia date from around 40,000 years ago, and there were houses as big as 20 square meters laid out with variable numbers of storage pits and hearths. In western Eurasia, carved Venus statuettes proliferated, and Upper Paleolithic cave and rock shelter art were produced from Altamira to Lascaux and beyond, near the coastal and inland rivers of northern Spain and southern France. Houses varied in size and structure, and graves – in cemeteries that included tens or hundreds of individuals – were richer or poorer. They probably belonged to more or less polygynous fathers.

Greater reproductive variance would have depended, as always, on a rich resource base. Some coastal groups exploited crustaceans or mollusks near oceans and left behind shellfish middens; others settled along inland rivers, where they left fish traps or baskets; some on the plains hunted mammoths, where they left mammoth bone architecture; others harvested and processed mass quantities of wild seeds and left mortars and pestles (Cummings et al. 2014). Many of those artifacts survive from comparatively recent times; other artifacts from the more distant past have inevitably been lost. Wherever edible plants and game animals were abundant, and along fish-rich and shellfish-rich rivers and coasts, societies should have been more sedentary, with more variance in status, wealth, and reproductive success.

Again, the genetic evidence is consistent. Geographically diverse samples of Y-chromosome sequences suggest a couple of reproductive bottlenecks over the course of human evolution. The first, from around 40,000 to 60,000 years ago, coincides with *H. sapiens*' move out of Africa into Eurasia by a small number of colonizers, when the effective breeding population expanded. More females than males contributed to that expansion: The effective breeding population among women was more than twice the effective breeding population among men.

Those differences took off with the Neolithic. A second bottleneck, from around 8,000 to 4,000 years ago, seems to coincide with an increase in sedentism, after *H. sapiens* started to practice agriculture. It overlaps with the origins of civilization. At that point, the effective breeding population among women became as high as 17 times the effective breeding population among men. In short, people became much more polygynous (Karmin et al. 2015).

High Polygyny

After the Neolithic, people settled into full-time farming groups. Many of the first civilizations were formed on areas of circumscribed

agricultural land: They were ecologically constrained. And by as early as 10,000 years ago, the first written accounts were being kept. Emperors consistently fathered children in triple digits, and many of their helpers or workers were facultatively or obligately sterile as a result.

Heads of the first civilizations were consistently reported to have sexual access to hundreds or thousands of women, and in a variety of sources – from Bible chapters to the names of “king’s bodily sons” on Egyptian scarabs, to passages from the Buddhist canon, to Chinese dynastic histories, to narratives by a pair of Inca mestizos, and to a history of Mexico commissioned from an Aztec noble – their children were numbered at over 100. Artaxerxes II (Mesopotamia) was remembered as the father of 118 sons; the names of 60 daughters and 96 sons of Rameses II (Egypt) are known; Ashoka “the Sorrowless” (India), the grandson of the first Hindu emperor, won his throne over the bodies of 100 brothers; the twelfth-century emperor, Huizong (China), was credited with 65 daughters and sons; Nezahualcoyotl, the governor of Texcoco who was a friend of the Mexican (Aztec) emperor Motecuhzoma I, raised 57 daughters and 60 sons, and Pachacuti “the World Seizer” (Inca) was remembered as the father of 300 or 400 children (Table 1 and Fig. 1; for historical references, see Betzig 2012, 2014).

The histories flesh those numbers out. In the Near East, in or around 2271 BC, Sargon the Great put Lugal-Zage-Si, the ruler of Umma, in a dog collar, and patched together an empire. But first, Lugal-Zage-Si overthrew Urukagina, the ruler of Lagash, who wrote: “The houses of the palace harem and the fields of the palace harem, the houses of the palace nursery and the fields of the palace nursery crowded each other side by side.” By the eighteenth century BC, upriver on the Euphrates at Mari, all of 232 women filled the palace of Zim-Rilim – who knew Hammurabi of Babylon. And when by the seventh century, on the Tigris, the Assyrian emperor, Ashurbanipal, left records of Harem Governesses and Weavers in his Nineveh library, he listed 13 governesses, 145 weavers, 52 maids, and 260 miscellaneous

women. The Persians were well known for their harems: Artaxerxes II is supposed to have fathered 115 bastard sons, besides three legitimate ones, and Sisygambis – who was the mother of Darius III and the mother-in-law of Alexander the Great – remembered that 80 of her brothers had been killed in a day. Those estimates fit with the first books put together by Hebrew scribes, who had Solomon collect 1,000 women and his son Rehoboam father 88 children (1 Kings 11:3, 2 Chronicles 11:21).

In Egypt, there were more polygynous men. In the Old Kingdom, when the twenty-sixth-century BC pyramid builder Sneferu went out for a row on his private lake, he took along 20 women with the shapeliest bodies, breasts, and braids, who had not yet given birth, and dressed them in fishnets. In the Middle Kingdom, the twentieth-century BC pharaoh, Amenemhat I, was done after a conspiracy in his harem: “Has discord been fostered within the palace?” And in the New Kingdom, pharaohs collected hundreds of women as tribute (“send very beautiful women, but none with shrill voices”), or as parts of their wives’ dowries (“marvels brought to his majesty”). So the tomb of the thirteenth-century BC pharaoh, Rameses II, held chambers for dozens of sons, and the names of his “king’s sons” and “bodily king’s sons” were written in stone. There were 96 of them, with another 60 or more daughters.

There was more reproductive variance in Asia. Chandragupta Maurya – who might have got a look at Alexander the Great when he was growing up – was the first to bring Indus and Ganges together under one yoke. Tradition had him follow an advisor, Kautilya, who put together an *Arthashastra*, or “Study of Gain.” It asks emperors to build women’s compartments, one within another, blockaded by a defensive wall and moat and circumambulated by three fires. An infirmary was supposed to be stocked with pharmaceuticals and potherbs, for midwives and medics, and nearby, dormitories were supposed to be built for princes and princesses: Bimbisara, who was Chandragupta’s successor, raised 100 sons in those rooms. Hundreds of years later, Vatsayana’s *Kamasutra*, or “Love Threads,”

advised Gupta emperors on how to recruit women. Some were enlisted by village headmen, who won over female villagers by just asking them, and others were conscripted by women already in the harem, who talked up the emperor at festivals in the palace. Compassionate rulers were encouraged to drink milk boiled with the testicles of rams or goats, so they might enjoy many women in a night. And compassionate consorts were persuaded to learn how to sing, dance, draw, sculpt, solve riddles, speak multilingually, practice magic, and make parrots talk, as an emperor may have thousands of other women competing for his attention.

Chinese dynastic histories offer lists of imperial children – 65 are mentioned for the Northern Song emperor, Huizong. But many emperors were supposed to have kept enormous harems and must have fathered more daughters and sons. When the man who unified China in 221 BC, the First August Emperor of Qin, connected his 270 palaces together, he filled them with more than 10,000 beautiful women that he’d taken from the feudal rulers, said China’s first historian, Sima Qian. That number would grow by an order of magnitude. Yangdi, the Sui dynasty emperor who built the Grand Canal and rebuilt the Great Wall, was credited by an official historian with 100,000 women in his secondary palace at Yangzhou, alone. Even before there was a first emperor, records made with the red brush kept track of the health and menstrual cycles of royal women: Court ladies led consorts to the bedchamber on correct calendar days and gave them a silver ring to put on their right hands; they switched the ring to their left hands after congress was accomplished, and consorts who conceived were rewarded with gold rings. And after the Qin brought China together, recorders of imperial intercourse were assigned civil service ranks – 6a under the Tang and 9a under the Song.

As in the Old World, so in the New. In the Valley of Mexico, the fifteenth-century AD *tlatoani*, or “Speaker,” of Texcoco, Nezahualcoyotl – poet, architect, engineer, and friend of the Aztec emperor Motecuhzoma I – had a zoo, gardens, music hall, and ball court in

his palace, where his women, reared in seclusion, raised his 57 daughters and 60 sons. Three generations later, Motecuhzoma II's palaces were indescribably marvelous to Hernán Cortés and the Europeans who came after him. The Spanish were able to get so many Aztecs to help them fight because Motecuhzoma's taxmen had carried off their daughters and wives – said Bernal Díaz del Castillo, who fought with Cortés as a young man. And Motecuhzoma's ancestors had fathered sons on so many women, because it fitted the dignity of a ruler – said Antonio de Mendoza, the Spanish viceroy. Emperors collected raw cotton and textiles, maize, and other staples as tribute, and “provinces that lacked foodstuffs and clothing paid in maidens” – said the Dominican friar, Diego Durán. It got so bad that “since the lords and chiefs stole all the women for themselves, an ordinary Indian could scarcely find a woman when he wished to marry” – said the Franciscan missionary, Toribio de Benavente Motolinía.

In the Andes, it was worse. Inca emperors kept estates all over their empire, and a third part of their revenue was spent on women. “A judge or commissioner named by the Inca was dispatched to each province, and his only responsibility was this matter of collecting girls” – said Bernabé Cobo, the Jesuit historian of New Spain. Houses of virgins were set up all over the empire, and “all of them had many children” – said the conquistador Pedro Cieza de León. Both Garcilaso de la Vega, who was the son of an Inca noble and a Spanish lord, and Juan de Betanzos, who was Spanish but married an Inca noble, suggested some numbers. In the generations before the conquest, the emperor Pachacuti had 300 or 400 children; the emperor Tupac Yupanqui had 300 children; the emperor Qhapaq Yupanki left over 250 sons and daughters, and the emperor Wayna Qhapaq left over 200 *sons*. Guaman Poma de Ayala, a son of Inca nobles, added that access to women was strictly prescribed by law. “Principal persons” got 50, *hunu kurakas* (heads over 10,000 households) got 30, *waranka kurakas* (heads over 1,000) got 15, *pachaka kurakas* (heads over 100) got 8, *chunka kamayuqs*

(heads over 10) got 5, and the “poor Indian” took whatever was left.

Archaeological evidence from the early empires is all over the place. In Mesopotamia, from the third millennium BC, the Great Death Pit in the Royal Cemetery at Ur contained the remains of six male bodyguards carrying knives or axes, with four women harpists, and the ordered rows of 64 women of the court laid out in ceremonial dress – short-sleeved scarlet coats – with carnelian and lapis lazuli on the cuffs, gold and silver necklaces, earrings, headdresses, and dog collars around their necks, and part of the fifth-century BC palace at Persepolis has often been referred to as a harem. In Egypt, the New Kingdom pharaoh, Akhenaten, put up north and south harems in his capital at Amarna, and several letters in his House of Correspondence asked subjects to “send very beautiful women, but none with shrill voices,” 10, 20, or more at a time, and at Thebes, the nineteenth dynasty pharaoh Rameses II's tomb included places for dozens of his 96 sons. In India, the third Mauryan emperor inscribed pillars and rocks all over his empire with reassurances that he would look out for his subjects, “whether I am eating or in the closed female apartments, in the inner chamber, in the royal rancho, on horseback or in pleasure orchards.” And in China, after the third Ming emperor moved the capital from Nanjing to Beijing, he constructed the Forbidden City; it would cover 180 acres and include 980 buildings (apocryphally 999), with nearly 9,000 (apocryphally 9,999) rooms.

So it would go in the New World. Nezahualcoyotl's compound in Texcoco covered over 200 acres and held over 300 rooms, and at the end of the Valley of the Incas, at Machu Picchu, there were over 200 buildings and over 100 burials that included a number of young women.

Genetic evidence is consistent, again. Samples of Y chromosomes from contemporary men suggest an expansion of three East Asian male lineages within the last half a millennium. Those clades show up with high frequency across populations and represent more than 40 % of contemporary Han Chinese. In other words,

roughly 300,000,000 living men are descended from just three ancestor males who lived around 6,000 years ago, in the late Neolithic Age (Yan et al. 2014).

Even more striking evidence suggests a strong genetic legacy of the Mongol emperors who ruled China for roughly a century. A Y-chromosome star cluster has been found in 8 % of all men from the Pacific to the Caspian Sea and in 1/200 of all men worldwide. It has been suggested that the star cluster originated in Mongolia approximately a millennium ago and has been carried on by male-line descendants of the Yuan dynasty ancestor, Genghis Khan (Zerjal et al. 2003).

Conclusion

The first *Homo sapiens* were hunters and gatherers. Some, like most twentieth-century foragers, lived in small groups and moved around a lot. Most of the reproductively successful foragers studied by contemporary demographers number their children in single digits. But many of them live in poor habitats, from the desert to the Arctic. Successful Pleistocene foragers who found and defended rich habitats – where edible plants and game animals were abundant, or along rivers and coasts – might have done better than that. They probably lived in larger societies and were less nomadic. And they were probably more polygynous. Archaeological evidence of sedentism goes back 100,000 years or more in Africa and the Near East, and genetic evidence suggests that, across much of the Pleistocene, the effective breeding population of women was larger than the effective breeding population of men, perhaps by a factor of 2/1.

Gardeners are almost always more sedentary than hunters and gatherers. And many semisedentary men – like the *caçiques* Christopher Columbus found all over the Caribbean, or the *tu'i* and *ali'i* and other Pacific Island chiefs who met James Cook – often have sexual access to a number of wives or slaves. In semisedentary societies studied by contemporary demographers, the most

reproductively successful fathers count their children in double digits. Reproductive variances for herder-gardener men are consistently higher than reproductive variances for herder-gardener women. And again, archaeological and genetic evidence extend those differences back in time. Across Eurasia, Upper Paleolithic shelters varied in size and structure, and burials were richer and poorer: They would have belonged to more or less polygynous fathers. As far back as the African Exodus of around 50,000 years ago, the effective breeding population of women was better than twice the size of the effective breeding population of men. By the late Neolithic, at around 4,000 years ago, after the origin of full-time farming, that ratio was as high as 17/1.

After the origins of civilization, polygyny increased, from the Far West to the Far East. Emperors consistently left children who approached triple digits. In the first written histories, in the book of Kings, Solomon collected a thousand women – 700 *sarah*, or noble women, and another 300 common women, or *piylegesh* – in his bronze and cedar palace, and Rehoboam, his son, became the father of 60 daughters and 28 sons. In histories from later centuries, emperors – from Egypt to India, to China, to the Valley of Mexico, and to Peru – collected hundreds, or thousands, or hundreds of thousands of women and consistently fathered over a hundred children. Many of their palaces still stand, from the ruins at Persepolis to the ruins at Machu Picchu, and in some of their tombs, places were saved for dozens of their sons. Other evidence survives on contemporary Y chromosomes. A star cluster sampled in 16 areas across Asia has been found in 1/200 of all early-twenty-first-century men. It may have originated in Mongolia, in a lineage founded by Genghis Khan.

Genghis' grandson, Kublai Khan – who was a friend to the Venetian traveler Marco Polo, and an inspiration to Coleridge – founded the Yuan dynasty that ruled China from AD 1271. In his *Travels*, Marco Polo remembered that this khan, who was the father of at least 47 sons, kept six women at a time in his bedroom: “And so

throughout the year, there are reliefs of maidens by six and six, changing every 3 days and nights” (Polo, *Travels*, 2.8–9). Half a millennium later, Coleridge ended his opium-inspired poem about the same emperor with these lines: “Weave a circle round him thrice,/And close your eyes with holy dread,/For he on honey-dew hath fed,/And drunk the milk of Paradise.” He was a highly polygynous man.

Definition

That what our words and sentences refer to, what we intend to convey when we utter sentences, or what we understand when we interpret utterances of others.

Introduction

Among those who think about the nature of meaning in human language are philosophers, linguists, and psychologists, and yet, meaning can still be seen as the most important unsolved problem in these disciplines (Fitch 2010). Numerous different answers to the question “what is meaning?” can be found in the literature, even if we look at philosophical literature alone. This text will give an overview of some of these accounts, starting with an example and some basic intuitions.

When I say “My bicycle is green” I use words to *refer to* an object in the world: my bicycle. But apart from the world, my utterance has something to do with what I think as well. By expressing it, I express a *mental representation* about my bicycle, and whoever hears the sentence will form a mental representation too. Finally, if I would utter the words “Mijn fiets is groen” to a speaker of Dutch, I know that this person will come to understand that my bicycle is green, just because he or she knows what the utterance means: There is an existing *convention* in the language I speak, to connect that meaning

to those words. In what follows I will describe three accounts of meaning in which these basic intuitions are reflected.

Propositional Meaning

Theories of meaning that take reference (and truth) as their central concept are all grounded in the work of Gottlob Frege. Frege (1892) developed his work on natural language against the background of a simple referential theory of meaning. The simplest conceivable theory of meaning in terms of reference defines the meaning of words as the object (or set of objects) they refer to. An example (from Speaks 2016):

1. Obama is the 44th president of the United States.

According to the referential theory of meaning, (1) is true because “Obama” and “the 44th president of the United States” refer to the same person. Similarly, the following sentence is not true, simply because “Trump” and “the 44th president of the United States” do not refer to the same person:

2. Trump is the 44th president of the United States.

A theory of meaning based on reference has the advantage that reference and truth are easy to formalize in a formal or mathematical framework. Reference alone, though, is not enough to form a proper theory of meaning of natural language. One of the problems that have been pointed out has to do with co-reference. Consider the following two examples:

3. John knows that Prince has died.
4. John knows that TAFKAP has died.

During a certain stage in his career, Prince performed under the name TAFKAP, so the names in (3) and (4) refer to the same person. However, John may not be aware of this, meaning that 3 could be true and 4 false, at the same time.

That is something a naive theory of meaning cannot account for.

More advanced theories of meaning (starting in the work of Frege, but for an overview of related approaches, see Speaks 2016) postulate a level in between the word level and the referent level, called *proposition*. Propositions are abstract objects that link words and their referents (and sentences to truth values), and they are often defined in terms of *possible worlds*. In possible world accounts of meaning, the meaning of an expression is not what it refers to in the actual world, but rather a rule that tells you what an expression would refer to *if the world were a certain way*. A simple example: The meaning of a referring expression such as “the tallest man in the world” will not simply be the man that happens to be the tallest, but instead, a recipe or rule for *finding* the tallest man in the world. The advantage of using possible worlds as the middle ground between words and referents is that they work well in formal and mathematical models of language, and a rich tradition of formal theories has been based on this approach. The formal models that are rooted in this approach to meaning are good at capturing the compositional properties of meaning: They show how meanings of individual words plus the way in which they are combined deliver complex, structured meanings. Giving an account of how human minds produce, convey, and process these complex meanings is not the primary goal of propositional accounts of meaning, though. Next, I will discuss an account of meaning that does focus on the mind.

Meaning and Intentions

An account of meaning that focuses more on the language user than on reference can be found in the work of Paul Grice. Grice (1969) defined meaning in terms of *intention*, by the following definition:

a means *p* by uttering *x* if and only if *a* intends in uttering *x* that

1. His audience come to believe *p*
2. His audience recognize this intention, and
3. (1) occurs on the basis of (2)

Thus, according to Grice, meanings of utterances are to be explained in terms of the intentions of their speaker. Moreover, this intention should be recognized by the hearer. As an illustration for this, consider the following example from Grady and Warner (2014):

Imagine you are stopped at night at an intersection, when the driver in an oncoming car flashes her lights. You reason as follows: “Why is she doing that? Oh, she must intend me to believe that my lights are not on. If she has that intention, it must be that my lights are not on. So, they are not.”

Grice’s view ties the meanings of words and sentences closely to the beliefs and mental representations of the language user. Because his work concerns the contexts in which utterances are used, and because of his related work on conversational implicatures, Grice is seen as the founding father of the linguistic subfield of *pragmatics* (see Korta and Perry 2015).

Meaning and Conventions

The two accounts of meaning I have discussed so far focus on very different aspects of language: One emphasizes the aspects of meaning that have to do with truth and reference and are easily formalizable, and the other focuses on language as a social phenomenon. According to David Lewis (1970), these simply represent two different topics, and *only confusion comes of mixing the two* (Lewis 1970, p. 19). Lewis (1975), however, does address these two intuitions simultaneously (but systematically), by starting from distinction between *languages* and *language* and subsequently devising an account of how the two can be connected.

- A. *Languages* can be defined as sets of strings (sentences) and meanings such that to each string a meaning is assigned (Lewis defines meanings in terms of possible worlds).
- B. *Language* is a social phenomenon, a sphere of human action in which speakers produce strings of sounds in order to bring about beliefs or actions in a listener.

Thus, on the one hand, Lewis maintains a very formal definition of meaning that connects sentences to abstract meaning entities, but he recognizes the social aspect of language use at the same time. Looking at linguistic communities in very general terms, Lewis observes that there are regularities between (1) the beliefs held by a speaker and the utterances they produce and (2) the utterances of a speaker and the beliefs or actions they bring about in their listeners. These regularities (or at least some of them), he postulates, are linguistic conventions. Observing that languages are sets of strings and their ascribed meanings (A), and language is a convention-governed social activity (B), Lewis then combines the two views in the following way:

A language *L* is used by a population *P*, if and only if there prevails in *P* a convention of truthfulness and trust in *L*, sustained by an interest in communication.

Truthfulness, in this definition, simply means to say that language users try not to utter sentences that are untrue; trust, on the other hand, represents the intuition that language users assume utterances of others to be true. To apply this to the bicycle example from the introduction, when I say “my bicycle is green,” I believe that my bicycle is green, and I know that this sentence, in English, is generally used to convey exactly that. In other words, I utter this particular sentence because it is true, *and* because I know that other people who hear it, will understand it. See Lewis (1975) for more detail, or Speaks (2016) for an overview of Lewis’s work compared to that of others.

The Evolution of Meaning

Some theorists implicitly conceive of meaning, or of language rules, as a stationary phenomenon, and not necessarily as something that can change over time. When we consider meaning in the context of the emergence and evolution of language, we can no longer hold on to that assumption. In what follows, I will sketch how the

accounts of meaning mentioned above connect to the language evolution debate.

It is not immediately obvious how the formal models that are rooted in truth and reference would fit in an evolutionary picture of meaning. However, they do point us to a property of language that is fundamental and needs to be accounted for in any (evolutionary) theory of language: Human language systems have propositional meaning; our sentences say things about the world that may be true or untrue. Fitch (2010, p. 121) even states that propositional meaning is one of the distinctive design features of language: *a central component of semantics that had to evolve for language in its modern sense to exist.* (pp. 121–122).

Although Paul Grice never discussed the emergence of language systematically, his later work (1975, 1982) discusses the difference between natural and nonnatural meaning. An example of natural meaning would be the usage of “means” in “Those spots mean measles.” This kind of meaning is factive: The spots cannot stop meaning measles. Natural meaning is contrasted with non-natural meaning, such as in “Those three rings on the bell (of the bus) mean that the bus is full.” This kind of meaning is nonfactive: The driver can ring the bell three times while the bus is not full at all. As an example of an in-between case, something that is a case of natural meaning but can grow towards nonnatural meaning, Grice mentions groaning. A groan is a natural sign of pain, when someone groans involuntarily. It is possible, however, to produce a groan voluntarily, to deceive the audience, and the perceiver will then be led to the conclusion that the groaner is in pain, but this happens on the basis of the natural meaning of groaning.

Grice only meant his analysis of groaning as a tentative example, but it brings a characterization of meaning in human behavior closer to the cognitive and communicative observations of animals (see Byrne and Whiten 1989 for a much cited overview of tactical deception in animals). And after all, when the evolution of language is considered, we cannot simply take meaning for granted, and we need well-defined concepts to talk about the transition from nonhuman to human meaning.

David Lewis's work has an explicit connection to evolutionary accounts of language. Lewis (1969) gives an account of how conventions emerge in a community and has laid the basis for mathematical models of the emergence of signaling systems in *evolutionary game theory*.

A key difference between Grice's and Lewis's accounts is that the former focuses mainly on the minds of language users and the latter on the public property of meaning to be grounded in a community. Recent work that discusses the origins of meaning has mainly focused on its cognitive roots (e.g., Jackendoff 2002; Fitch 2010), but accounting for the emergence of meaning in terms of communication and conventions forms an interesting alternative. For instance, Schouwstra (2012, Chap. 3) focuses on two possible sources for the property of *compositionality* in natural language. One postulates that compositionality comes from cognitive biases and was mapped onto language structure in an early stage of language emergence; the other postulates that compositionality is the result of mechanisms of cultural evolution that work on a non-compositional starting point.

Conclusion

Utterances are used to refer to things in the world, to express mental representations (or change those of others), and they rely on conventions that exist in language communities. These intuitions about language can be seen in three main accounts of meaning in philosophy and linguistics. When the evolution of language and meaning are considered, it may not be enough to focus on only one tradition; instead, combining insights from these different emphases is probably necessary to arrive at a complete picture of the emergence of meaning.

Meaning Making and the Self

Christoforos Christoforou
University of Nicosia, Nicosia, Cyprus

Consciousness; Phenomenological self; Self-agency; Self-concept; Subjectivity

Definition

The construct of self refers to a distinct and coherent mental space of subjectivity that is organized around time, place, and space and which enables humans to reflect on their experiences and maintain a sense of agency, order, and continuity throughout their life.

Introduction

The self is an organic and intrinsically dynamic construct that is constantly evolving and adapting to the complex and dynamic interactions between an individual's internal and external experience (Bonovitz and Harlem 2018). The construct of self refers to the formation of a coherent mental space of subjectivity that is organized around time, place, and space and which enables humans to reflect on their experiences and maintain a sense of agency, order, and continuity throughout their life (Beni 2019). Moreover, this mental space of subjectivity implies a sense of distinctiveness that facilitates the phenomenological differentiation between self and others. Therefore, the self can be functionally conceptualized as the integration of symbolic and sensory-motor representations of internal and external experience into a cohesive sense of a purposive agent. The ability to construct sensory-motor and symbolic representations is intrinsically dynamic and thus constantly evolving organically from birth onward (Labouvie-Vief 2005).

Development of Self and Its Relation to Meaning Making

Humans are born with a biological predisposition for strong affective bonds. The quality of those affective bonds interacts with the infants' genetic endowment and thus influences to a significant extent the developmental trajectory of self (Bonovitz and Harlem 2018). More specifically, the foundational substrate of the self emerges out of the affective sensory-motor contingencies that are constructed during the period of infancy (Riva 2018). The internal and external experiences of

the infant are organized around those affectively charged sensory-motor contingencies, which in turn acquire a structural function and thus shape the sense of one's subjectivity and agency (Beni 2019). That is, in the context of early attachment bonds, infants construct affectively charged sensory-motor schematic representations that are organizing their experiences into pleasurable, unpleasurable, and painful (Labouvie-Vief 2005). These schematic representations enable infants to order their internal experience in terms of phenomenological quality and anticipate similar experiences. In other words, once a schematic representation is constructed, it functions as a lens through which experiences are processed, categorized, and responded to similarly over and over, thus enabling the self to make meaning and adapt to the specifics of its environment. Therefore, regardless of the quality and the degree of complexity of later experiences, the self's sense of agency and subjectivity is significantly shaped by the affectively charged sensorimotor representations that the infant had constructed within the context of early attachment bonds during the early stages of her/his life (Whitebread and Grau 2019).

The Body as a Container of the Self

Moreover, the dynamic interaction between the soma and the external world during the first year of life enables the construction of a psychological space within which somatosensory, affective, emotional, cognitive, and symbolic activity can be held and reflected upon (Feldman 2002). Specifically, during infancy, new-borns have the important task of constructing a mental representation of the skin as a container of their body. The somatosensory experience of their body skin provides them with a psychological frame that enables them to cultivate and gradually solidify a sense of internal and external experience as well as a boundary that distinguishes between the two of them (Riva 2018). Specifically, the body skin provides the foundation for the gradual cultivation of a sense of internal space which is contained within one's body. This is, in turn, cultivates the phenomenological differentiation between the experience of the world, the self, and others (Riva 2018).

Relational Qualities of the Self

Furthermore, neuroscience findings strongly indicate that alignment in attachment bonds constitutes a core quality that provides the underlying substrate for the formation of a functional sense of self (Thompson and Batchelor 2017). Specifically, by becoming attuned to the internal states of the infant's mind, the responsive caregiver provides to the baby a secure, stable, reliable, and predictable environment in which the former feels safe to explore the self while interacting with the world (Fonagy 2002). Moreover, through the experience of emotional attunement and their capacity to use their body, infants become gradually able to identify as well as to set in motion spatiotemporal contingencies (Riva 2018). Through these spatiotemporal contingencies, infants begin to categorize their environment into animate and inanimate objects through the construction of intentional connections with and between perceptual objects. This dynamic process enables infants to develop a sense of a distinctive and unique existence within time, place, and space, which in turn provides the context for the gradual formation and solidification of a sense of self (Scalabrini et al. 2018).

Mentalization, Meaning-Making, and the Self

Mentalization is a functional process that allows people to make use in an integrated manner their perceptual, inferential, and imaginative capacities to reflect on and comprehend the qualitative operations that influence one's and other peoples' idiosyncratic mental functioning (e.g., belief system, incentives, feelings) (Fonagy 2002). Therefore, the capacity for mentalization enables humans to reflect on the phenomenology of the experience of themselves and others and thus fosters to a significant extent the construction of psychological meanings (Luyten et al. 2020).

The responsive caregiver who creates a predictable environment in which the communications and experiences of the infant are empathetically ascribed with needs, intentions, desires, and feelings provide an experience to

the child's self with another who can integrate her/his subjective experience into meaningful narratives (Whitebread and Grau 2019). This dynamic process instills in to the child a sense that her/his intentionality and subjectivity is acknowledged, appreciated, and validated which in turn enables the child to connect to herself as an intentional, real, and integrated agent whose experience is meaningful and can be communicated (Fonagy 2002).

Operational Processes of the Self

In addition, neuropsychological findings indicate that there are qualitatively distinct and dynamically interrelated operational mechanisms of the self that are embedded in underlying activities of brain structures and predispose humans to develop and preserve the qualities of consciousness and subjectivity (Beni 2019). Specifically, neuroscientific research has consistently indicated that the activities of the brain are marked by spatiotemporal contingencies (Scalabrini et al. 2018). This implies that the integration of all stimuli, whether they are sensorimotor, emotional, perceptual, or interpersonal in nature, as well as their primary external properties, must be encoded within the operational context of the brain's internal activity (Thompson and Batchelor 2017). The functional quality of this integration determines to a significant extent how an individual is implicitly and explicitly processing external and internal stimuli, and thus, how she/he subjectively experiences internal and external reality (Scalabrini et al. 2018).

Self-Constitution, Self-Manifestation, and Self-Expansion

Self-constitution reflects the underling foundation of subjectivity and the psychophysiological processes of consciousness (Scalabrini et al. 2018). It involves the construction and meaningful integration of the body schema with a sense of agency and intentionality within time, place, and space. Moreover, it is associated with the construction of a mental representation of the self, which provides

an internal space of subjectivity and enables the differentiation between self and other, phantasy and reality, and thus between the internal and external experience (Scalabrini et al. 2018).

Self-manifestation reflects the operational manifestation of subjectivity and consciousness within time, space, and place in the here and now. It involves the functional mechanisms of perception, motivation, and cognitive-affective mentalization of self and others (Scalabrini et al. 2018). Self-manifestation emerges through the interaction between the processes of assimilation and accommodation (Labouvie-Vief 2005). Specifically, through the dynamic interaction between the processes of accommodation and assimilation, the extent of integration and complexity of the representations of self and others increases gradually (Whitebread and Grau 2019). Moreover, the processes of accommodation and assimilation, in conjunction with the constitutional drive for equilibrium and self-constancy, enable the individual to interact in a meaningful manner with the world and thus adapt to the specifics of it. Specifically, the state of equilibrium in the organism constitutes the driving force for the regulation and integration of ambivalent feelings that stem from conflictual environmental experiences (Labouvie-Vief 2005). The attempt to achieve order, control, and mastery reflects the psychological manifestation of the organismic proclivity to maintain a state of equilibrium as it enables the self to process and make meaning of external stimuli and thus adaptively respond to them (Scalabrini et al. 2018).

The integration of representations of self and others provides a functional framework for the construction of a complex perceptual template, which allows the individual to create subjective meanings about the self, the world, and its people (Labouvie-Vief 2005). Additionally, neuroscientific findings indicate that relational representations are stored in procedural memory (Thompson and Batchelor 2017). The procedural memory refers to a type of implicit and long-term memory system which stores unconscious knowledge regarding procedural ways of relating to other people as well as how to do things (Labouvie-Vief 2005). Furthermore, several research studies have indicated that the unconscious knowledge that is stored

in procedural memory regarding the operational qualities that govern the relationships of the self with others might be dynamically influencing the limbic-frontal circuitry, which is involved in motivation, affects, learning, and memory. This implies that relational representations of self and others might shape to a significant extent the processes of emotion-regulation, which in turn influence the way one's process experiences and responds to intrapsychic and interpersonal stimuli throughout her/his life (Whitebread and Grau 2019).

Self-expansion is associated with the integration of the functional dynamics and the operational properties of the self within an experiential time framework (Scalabrini et al. 2018). Specifically, the autobiographical, relational, semantic-symbolic, and psychological aspects of the self become integrated and then are coordinated within complex mental-conceptual structures (Beni 2019). This process of integration within an experiential time framework brings increasing differentiation between self and others within the time framework of the past, the present, and future experiences of the self. It thus regulates the narrative process of the individual (Scalabrini et al. 2018). Specifically, self-expansion reflects the ability for perceptual processing that integrates the past, the present, and the future and thus the capacity to experience and regulate ambivalent affects through the construction of coherent narratives (Labouvie-Vief 2005).

Conclusion

The self has the capacity for subjectivity, and it integrates implicit, explicit, and intentional states of being. The notion of the self is meaningful only when it is considered within the environment in which the self depends and to which must connect through the construction of psychological, social and cultural meanings (Thompson and Batchelor 2017). One of the core operational functions of experience reflects the process of ascribing meaning upon it. For instance, an experience is idiosyncratically processed by the explicit and implicit operational mechanisms that delineate the construct of the self. This dynamic process

motivates the self to highly idiosyncratic psychological reactions as well as purposive actions. Therefore, meaning-making, physiological and psychological needs, motivational forces, and affective experiences are dynamically interconnected and associated with the construct of self (Thompson and Batchelor 2017).

Measure of Relatedness

- R = Coefficient of Relatedness

Measurement: Categorical Versus Continuous

Elaine Scharfe

Trent University, Peterborough, ON, Canada

Definition

Attachment researchers have developed both categorical and continuous measures of attachment, for both theoretical and methodological reasons. More evidence is needed to evaluate whether attachment strategies are fundamentally categorical or continuous in nature.

Introduction

The first assessments of both infant and adult attachment were, without exception, categorical and found to be powerful predictors of behavior. Although there has been some debate as to whether attachment would be best assessed using categorical or continuous measures, as well as the development of continuous measures, the question – is attachment categorical or continuous? – is far from resolved.

Measurement of Attachment

Bowlby's theory of attachment gained considerable momentum when Mary Ainsworth first published, the Strange Situation (SS), an observation method of categorizing infant attachment (Ainsworth et al. 1978). The SS has become the gold standard for measuring infant attachment and the original three categories have endured (secure, anxious/resistant, and avoidant). Over the years,

there have been a few revisions to Ainsworth's original three category model, including the well-accepted addition of a fourth category (i.e., disorganized). Despite some attempts to revise or revisit, infant attachment continues to be viewed as a phenomenon that should be categorized. This insistence on categorization includes methodologies, which could be analyzed using continuous data analytic techniques (e.g., Waters and Dean's Q-sort), but are typically used to categorize infants into secure or insecure categories. There are also several assessments of preschool and school-age attachment which also categorize children into secure or insecure groups. Despite the limitations of categorical measures, from a statistical power perspective, the findings with infant attachment categories are consistent and strong.

Bowlby was quite clear that attachment representations were important "from the cradle to the grave" (Bowlby 1969/1982, p. 208) and in the mid to late 80s researchers began to explore the possibility of reliably measuring adult attachment. Research on adult attachment began with two independent and somewhat different approaches and the two methodologies remain somewhat at odds. First, Main and colleagues developed an interview-based assessment of adults' attachment of their family of origin from a sample of parents of 6-year-old children (Main et al. 1985). The children's attachment had been assessed at 1 year, and the parents' attachment categories were determined by comparing the parents' responses to the interview questions about their own family of origin when their child was 6 years old with their child's attachment category when their child was 1-year-old. Main et al.'s Adult Attachment Interview (AAI) continues to be the primary method of assessing adult attachment in developmental and clinical fields despite the time consuming training and coding of attachment interviews (see Hesse 2016 for a summary). The interview coding protocol which assesses individuals' coherence of their current state of mind with respect to their families of origin (past-focused) results in classification into one of four attachment categories: Autonomous (Secure), Dismissing, Preoccupied, and Unresolved/Disorganized. Over the past three decades, the AAI categories

have proven to be powerful predictors of parenting behavior as well as health and wellness, psychopathology, and romantic relationship outcomes.

Meanwhile, Hazan and Shaver (1987) introduced a simple three-paragraph forced-choice self-report measure of adult attachment using Ainsworth's infant categories as a template and envisaged "how" those infants would behave, in their adult romantic relationships, when they grew up. Hazan and Shaver's three-category measure of current romantic relationships, which differs from the AAI in several ways (i.e., self-report survey, assesses romantic relationships, is present-focused), was met with both enthusiasm and concern by personal relationships researchers. Although no one would question that the measure was ingenious, both in concept as well as in simplicity, researchers expressed immediate concerns with the limitations of this categorical paragraph measure and set out to develop continuous assessments of adult attachment. In fact, most of the debate, concerning whether attachment should be assessed using categorical or continuous measures has been generated from personal relationships researchers.

Over the next decade, several measures of adult attachment were developed but three measures seem to have stood the test of time. First, Bartholomew proposed a four-category model of attachment which highlighted Bowlby's proposition that adult internal working models of attachment developed from a view of the self as worthy of love (or not) and a view that others could be trusted and relied on for help (or not) when distressed, ill, or afraid (See Bartholomew and Horowitz 1991; Griffin and Bartholomew 1994). Bartholomew proposed that these underlying dimensions interacted (self/anxiety and other/avoidance) and resulted in a four-category model – highlighting that this model resulted in two avoidant styles: fearful avoidant (similar to Hazan & Shaver's avoidant category) and dismissing avoidant (similar to Main et al.'s avoidant category). Although Bartholomew's model gained popularity as a measure of both attachment in family of origin and current relationships, the measurement of the model proved

difficult. The time consuming nature of the interview coding proved unwieldy for social and personality researchers who desired large samples to gain sufficient statistical power for their multivariate analyses. Bartholomew also proposed two surveys: the categorical Relationship Questionnaire (RQ) and the continuous Relationship Scales Questionnaire (RSQ). The self-report surveys were more popular than the interviews; however, some researchers questioned the utility of Bartholomew's categorical measure (RQ) despite the strength of the early findings, including stability over time (see Scharfe and Bartholomew 1994). Although the continuous measure proposed by Bartholomew (RSQ) also proved to be moderately to highly stable over time, the scales had lower than desired reliability.

To improve the reliability of self-report attachment measures, Brennan and colleagues developed the Experiences in Close Relationships scale (ECR) using a subset of 323 items which assessed 60 attachment constructs from 14 scales. The resulting factor analysis of the items suggested that there were two orthogonal dimensions: attachment anxiety and attachment avoidance (Brennan et al. 1998). These ECR dimensions were found to have improved reliability compared to the RSQ scales, but the ECR was criticized as an inadequate measure attachment security (see Fraley et al. 2000) and an imprecise assessment of Bartholomew's four-category model (see Mikulincer and Shaver 2007, p. 97). Fraley et al. (2000) reanalyzed the Brennan et al. (1998) data and suggested two revised anxiety and avoidance dimensional scales in the ECR-R but nevertheless concluded that the ECR-R scales were still limited primarily due to the limitations of the existing item pool.

These measures – Bartholomew's RSQ (Griffin and Bartholomew 1994), the ECR (Brennan et al. 1998), and ECR-R (Fraley et al. 2000) – continue to be well used in the literature and each of the three scales have proven to be a powerful predictor of individual differences. Interestingly, researchers are drawn to Bartholomew's four categories and interpret attachment data, regardless of the scale used, using the theory underlying this four-category

model (e.g., neither the ECR nor the ECR-R were developed to assess the four-category model; see Mikulincer and Shaver 2007).

Categorical or Continuous?

Scientists from diverse disciplines have philosophized about and tested the pros and cons of categorical versus continuous measurement. These musings are also part of the fabric of attachment research. Both the SS and the AAI are traditionally categorical approaches, and both categorical methods produce strong results. Social and personality researchers tend to use continuous scales – of the four-category model or the underlying dimensions of attachment anxiety and avoidance – but this choice of continuous measures may be influenced more by their use of multivariate statistical techniques that require continuous variables and/or large samples rather than a philosophical stance on categorical versus continuous measurement. Interestingly, despite the use of these continuous measures and multivariate techniques, many researchers still tend to categorize the data or interpret the data using categorical (e.g., secure individuals) rather than continuous (e.g., security) language.

The problem with categorical thinking – which has been discussed in other fields – also plagues attachment research, and there are many reasons why categorizing attachment may limit researchers' ability to fully understand that importance of attachment representations. First, attachment categories may misclassify some individuals near the boundaries thereby increasing statistical error and reducing the power to detect the effects of particular attachment categories. Somewhat related, it has been suggested that the use of predominant categories may underestimate sex differences in attachment; sex differences are more commonly reported when using continuous measures of attachment. Second, the baseline proportions of attachment categories in clinical and nonclinical groups are different, highlighting that there may be categories that are more or less important depending on the sample or experience of the participants. Likewise, individuals in

clinical samples tend to have lower baseline proportions of secure attachment; however, the degree of security for individuals in clinical samples may be highly associated with coping or success of interventions. Third, categorization assumes that individuals' strategies are "black or white"; however, a more flexible use of different strategies may be more successful. Specifically, Bowlby originally proposed that attachment representations are "survival" strategies, and it may be that the most ideal strategy, in some situations or with some social partners, may include behaviors from two or more attachment representations. Since many infants have one primary caregiver, it may make sense that infants develop one predominant attachment strategy, but adults typically have multiple attachment figures and their internal working models of attachment are correspondingly more sophisticated. Adults may be expected to have developed different attachment representations with their different attachment figures and therefore might not fit nicely into one category. Further work is needed to test when this flexibility is adaptive. Finally, it is important to note that correlational techniques do assume that there is a linear relationship. A more complete exploration of the benefits of categorical versus continuous methods may help to detect nonlinear relationships.

Conclusions

Attachment researchers have developed both categorical and continuous measures of attachment and have only recently begun the dialogue about the pros and cons of categorical versus continuous measurement. In many ways, the choice – categorical or continuous – seems to be one of convenience rather than a decision rooted in theory or empirical evidence. In particular, developmental and clinical researchers, who tend to work with traditionally categorical approaches such as the SS and the AAI, are, of course, satisfied with these categorical methods as they tend to produce strong results. Social and personality researchers who tend to use continuous scales may be influenced more by their use of multivariate statistical techniques that require continuous

variables and/or large samples; however, many of these same researchers interpret the data using categorical (e.g., secure individuals) rather than continuous (e.g., security) language. To fully examine whether attachment is a categorical or continuous variable, researchers need to, in part, provide empirical evidence to support the question (see recent work by Chris Fraley and colleagues). This empirical work could focus on the effects of misclassification, underestimates of differences using categorical measures, importance of sample or experience of the participants, effect of the degree of security (or insecurity), benefit of a flexible use of several attachment strategies, and a more complete examination of linear and nonlinear relationships.

Life satisfaction; Satisfaction with life; Welfare; Wellness

Definition

Approaches to the psychometric measurement of human well-being.

Introduction

In psychology, well-being has been defined as “a person’s cognitive and affective evaluations of his or her life” (Diener et al. 2002, p. 63). Within this definition, the cognitive element refers to what an individual thinks about his or her life both as a whole and in domain terms (i.e., in

specific areas of life such as environment, career, relationships), whereas the affective element refers to emotions, moods, and feelings. Similarly, Huppert (2009) considered well-being as the combination of feeling good and functioning effectively. Various instruments have been developed to measure general psychological well-being such as the *Satisfaction With Life Scale* (Diener et al. 1985).

The Measurement of Well-being

Affect is considered positive when the emotions, moods, and feelings experienced are pleasant (e.g., joy, elation, affection) and is deemed negative when the emotions, moods, and feelings experienced are unpleasant (e.g., guilt, anger, shame). A focus on the affective element is known as a hedonic approach to well-being, originating with the Greek philosopher Aristippus, around 400 BC, who believed that the goal of life is to experience maximum pleasure. This view is typically also central to classical utilitarian philosophers in line with the maximization of pleasure (positive affect) and minimization of pain (negative affect). A focus on the functioning element is a *eudaimonic* approach to well-being, originating with Aristotle over a century later. Aristotle considered a purely hedonic happiness to be a vulgar and superficial idea, instead advocating that true happiness is found by leading a virtuous life and realizing potential. These two sides to the phenomenon of well-being are still prominent in the modern debate on defining well-being. In 1948, the World Health Organization (WHO) developed a definition of health as “a state of complete physical, mental, and social well-being – not merely the absence of disease or infirmity.” It has since been argued that this definition was not good enough in line with a eudaimonic approach. In the year 2000, it was put forward that this should include the ability to lead a socially and economically productive life. Indeed, the current WHO definition of mental health includes “a state of well-being in which the individual realizes his or her own abilities,

can cope with the normal stresses of life, can work productively and fruitfully, and is able to make a contribution to his or her community (World Health Organization, 2005).” Furthermore, the practice of considering people who are *Not currently engaged in Education, Employment, or Training* (the acronym NEET is typically applied) as not mentally healthy has become common in many countries such as the United Kingdom and Japan. A NEET individual is someone who is unwilling to work or receive any education or training, and typically lives at home supported by another person or people (often parents). Many of these are physically, mentally, and even socially healthy, but are not productive.

Components of Well-Being

A eudaimonic approach to well-being is central to humanistic psychology, with the key assertion that people have free will and make choices which influence their well-being. In particular, this approach involves the *actualizing tendency*: a fundamental motivation towards self-fulfillment and growth. Underlying this claim is that motives exist to pursue well-being. Indeed, motives can be defined as internal states, triggered by certain needs, which promote thoughts and behavior towards specific goals to rectify such deficiencies (Larsen and Buss 2008). The humanistic psychologist, Abraham Maslow, proposed a hierarchy of five human needs which must be satisfied to achieve well-being: physiological needs, security needs, belongingness needs, esteem needs, and self-actualization needs. The most fundamental and basic four layers of the hierarchy contain what Maslow termed “deficiency needs” which, if not met, will cause an individual to feel anxious and tense and motivated to seek their satisfaction. These needs may be most central to the hedonic element of well-being. The highest level of need, self-actualization, refers to an individual’s desire to realize and achieve their full potential in line with the *eudaimonic* element of well-being. Psychometric measures of Maslow’s hierarchy include the *Need Satisfaction Inventory* (Lester 1990) and the *Need Satisfaction Schedule* (Lollar 1974).

More recently, psychologists have built upon Maslow’s idea from an evolutionary perspective. Kenrick et al. (2010a) argue that Maslow’s hierarchy, although effectively capturing core aspects of human nature and development, is insufficient to capture the specific problems involved in human survival and reproduction. In their paper, the authors first support the notion of a hierarchical model of motivation and then expand the model to place successful reproduction as the primary goal underlying all human motivations. The resultant model incorporates seven levels of needs: parenting/kin care, mate retention, mate acquisition, status/esteem, affiliation, self-protection, and immediate physiological needs.

Kenrick et al. (2010a) base much of their theorization on Life History theory. The premise of Life History theory is that resources (including time and attention, as well as physical resources) are always limited and that development involves trade-offs in when and how to allocate resources (Figueredo et al. 2006). Within a Life History theory framework, behaviors are commonly divided into two broad categories: somatic effort and reproductive effort. Somatic effort is the energy expended to build the body and an adequate resource/skill base for survival (and consequently future reproduction) whereas reproductive effort is directly devoted to replicating the individual’s genes. Put another way, investment in somatic effort promotes the survival and reproductive potential of the organism and is therefore essentially an investment in future reproduction (more or higher quality offspring in the future) rather than current reproduction. Kenrick et al. (2010a) propose that the lower four stages of their hierarchy (status/esteem, affiliation, self-protection, and immediate physiological needs) are highly consistent with somatic effort, whereas the extensions they propose (parenting, mate retention, and mate acquisition) center on incorporating aspects of reproductive effort more firmly into the model. In other works in this area, the motive of *disease avoidance* has been incorporated with less attention given to *physiological necessities* (Kenrick et al. 2010b; Neuberg et al. 2010). Recently, a psychometric

measure of this fundamental motive system from a social standpoint has been developed by Neel et al. (2016).

Conclusion

Within psychology, well-being is measured from various approaches, typically stemming from different theoretical starting points. Broadly speaking, psychological well-being refers to an individual's subjective evaluations of their life, although productivity/functioning is widely advocated as important for true well-being, independent of positive affect and physical health.

General psychological well-being can be measured using short global satisfaction instruments such as the *Satisfaction With Life Scale* (Diener et al. 1985), whereas a breakdown of the components of well-being depends on the theoretical approach, such as a hierarchy/taxonomy of fundamental needs or fundamental motives.

Mechanisms to Detect and Punish Cheaters

Stefan Pfattheicher¹ and Robert Böhm²

¹Department of Social Psychology, Ulm University, Ulm, Germany

²School of Business and Economics, RWTH Aachen University, Aachen, Germany

Synonyms

Cheater detection; Defectors/sanctions/violation of social contract

Definition

Cheating violates shared social contracts. Individuals are sensitive to such violations and punish transgressors.

Introduction

Cheating can be broadly defined as any action that violates a social contract (e.g., a shared social norm) and that is intended to obtain personal benefits while inflicting costs on other individuals who have not agreed upon these costs (Cosmides 1989). Cheating occurs in many different contexts – in intimate relationships or in social groups where mutual cooperation increases collective benefits, while cheating benefits only the defector. Consider, for instance, a dyadic interaction in which someone pretends to behave cooperatively, leading another to behave cooperatively as well to maximize collective benefits. In this situation, the first person can exploit the cooperative other by defecting, thus benefiting oneself but inflicting costs on the cooperator. In this regard, incentives are provided for every individual to cheat on the social contract of mutual cooperation, especially when detection rates are low (Trivers 1971).

Detection of Cheaters

Since cheating decreases the relative fitness of cheated-on individuals and social groups as a whole, it is important for them to detect and punish cheaters, particularly in repeated social interactions. Therefore, it is likely that mechanisms to detect cheaters have been selected in human evolution. In order to differentiate between cheating and non-cheating in the first place, individuals must be sensitive to the rules and norms of *social* contracts (Cosmides and Tooby 1992). Individual sensitivity to social contracts can be illustrated clearly with the Wason selection task. In this task, one has to test a social rule, for instance, “If you are drinking alcohol, then you must be over 18.” Four cards are then presented, each with an age on one side and a beverage on the other side, say “16,” “drinking beer,” “25,” and “drinking coke.” The task is to identify the cards that possibly violate the rule. People are typically adept at selecting the correct cards (“16” and “drinking beer”). However, when the same exact task is presented in a less social and more abstract way, for instance, “If a person has a ‘D’ rating, then his documents must be marked code ‘3,’” with cards that read “D,” “F,” “3,” and “7,” then people are typically less adept at selecting the correct cards (“D” and “7”). Hence, individuals have an enhanced sensitivity to violations of social contracts (Cosmides and Tooby 1992).

Cheaters have incentives to mask their cheating, as other individuals are prone to punish and inflict costs on those who violate social contracts. Therefore, people should be sensitive toward the lies of others. Not telling the truth benefits the liar but typically inflicts costs on the interaction partner(s). As such, identifying cheaters in this context, that is, identifying who is telling the truth and who is lying, is important from an evolutionary fitness perspective. However, a recent analysis included several studies and demonstrates an accuracy rate only slightly above chance (54%) when judging whether a statement was true or false (Bond and DePaulo 2006). It is argued that mainly the absence of diagnostic cues and the interpretation of wrong cues (e.g., focusing on nervous facial expressions

instead of logical consistency and plausibility of content) are reasons for poor lie detection accuracy in humans.

Individuals are better in remembering cheaters once they have been identified as such. Although there seems to be no general face recognition advantage of cheaters, it has been shown that people are better at remembering that a face is associated with cheating than that a face is associated with neutral or cooperative behavior (e.g., Buchner et al. 2009). This source memory advantage has been attributed to (1) a greater sensitivity toward negative than positive information and (2) the enhanced memory for information that is emotionally incongruent with the individual's expectation. Accordingly, cheaters are more likely to be remembered if cheating occurs unexpectedly, e.g., if the interaction partner appears at first trustworthy or if the cheater is an in-group (vs. out-group) member (cf. Hechler et al. 2016).

Punishment of Cheaters

In small groups, continuous and repeated interactions between individuals are likely. Therefore, individuals should be prone to punish cheaters once they have been detected to prevent future cheating. Indeed, there is convincing evidence from evolutionary psychology and anthropology, as well as behavioral economics, that cheaters on social contracts are punished (Balliet et al. 2011).

Whether or not a cheater is punished depends on the individuals' sensitivity to cheating on social contracts (Pfafftheicher and Keller 2013). Consider the essential social contract of mutual cooperation in which defectors obtain, on the short term, higher benefits compared to cooperators. In this context, strong reciprocity evolved, describing the tendency to punish cheaters and to reward cooperators (i.e., non-cheaters) at personal cost, leading to the reduction of cheating behavior (Balliet et al. 2011).

Since cheating violates shared social contracts, and while it is important for individuals that these contracts are followed, individuals react with emotion to cheating. The emotion of anger (but not other basic emotions like sadness) is

consistently reported as the emotion that drives punishment of defectors that have cheated on the social contract of mutual cooperation (e.g., Srivastava et al. 2009).

Conclusion

Humans' high levels of cooperation and pro-sociality manifest in a sensitivity to detect cheaters who violate social contracts. When cheaters are detected, individuals are prone to punish the transgressors, even at their own expense. Punishment is important as it reduces the occurrence of cheaters by inflicting costs on them; as such, it is beneficial for social groups to incorporate group members who bear the costs and engage in punishment of cheaters, leading to a selective advantage in the course of evolution (Boyd et al. 2003).

Preferring to form coalitions with individuals who possess certain traits.

Introduction

The conditions under which coalitional aggression is adaptive readily suggest that coalition members ought to prefer certain traits in their coalition partners. Tooby and Cosmides (1988) describe coalitional aggression as a special case of multi-individual cooperation where collective

action entails risk. Tooby and Cosmides (1988) identify two broad adaptive problems that arise due to the intrinsically risky nature of aggressive coalitional acts such as warfare. The first problem is judging the probability of one's coalition attaining success in an aggressive encounter and adjusting one's willingness to participate accordingly. The second problem is judging one's private level of risk relative to the risk faced by other members of one's coalition. When one's own risk exceeds that faced by one's comrades, there is a greater chance that one's costly participation will yield benefits that accrue to one's comrades rather than oneself – that is, unequal risk within a coalition allows some members to parasitically free ride on the efforts of others. To solve these adaptive problems, coalitional actors must possess mechanisms to judge and prefer certain traits in their partners: traits that increase the fighting ability (formidability) of the coalition and traits that are indicative of willingness to participate in aggression despite the risks of doing so, such as courage and bravery.

Judging Coalitional Ability

If coalition partner preferences function adaptively, then those preferences should lead judges to reliably identify individuals who actually perform well in coalitional conflict. Berkun and Meeland (1958) report the results of a study conducted with US infantrymen deployed to Korea in 1953 which suggests that men are able to accurately judge coalition-relevant traits in other men. The combat performance of soldiers was rated by their peers and corroborated by observed combat incidents. These ratings were used to classify soldiers as “fighters” or “non-fighters.” The soldiers were then randomly distributed into new groups made up of people whom they did not know beforehand, which allowed for new impressions to form over the course of living together for 1 week. Although the groups resided behind the frontlines of battle and group members were not informed of each other's combat history, soldiers judged individuals previously classified as nonfighters to be least desirable as comrades in

a combat situation, while fighters judged other fighters to be the most desirable comrades. Thus, soldiers' judgments must have been based on cues that were reliably associated with the targets' previous combat histories.

Coalitional Contribution and Social Status

Winegard et al. (2014) argue that evolved preferences regarding coalition partners manifest in social status systems that allocate prestige to men who contribute to coalitional success. Winegard et al. (2014) point out that in many cultures, men, the primary actors in coalitional conflict, are specifically honored for displays of physical strength and fierceness and shamed for displays of timidity and cowardice. Allocating prestige in this manner not only incentivizes men to cultivate traits that increase coalitional success but also discourages free riding by denying benefits to men who have not or are not likely to contribute to coalitional action.

The connection between a man's social status and his coalitional contributions posited by Winegard et al. (2014) is supported by anthropological evidence. For example, Chagnon (1988) reports that among the Yānomamö, an Amazonian tribe that commonly engages in intergroup raiding, valiant behavior is celebrated, and men who have killed earn the status-elevating title of *unokai*. Additionally, Yānomamö men who frequently avoid participation in raids are shamed for their cowardice (*téhe*). Patton (2000) used informant reports to quantify the social status and capability as a warrior of men from Conambo, another Amazonian site where coalitional violence is common, and found that warrior ability was strongly predictive of social status.

Preferences for Traits in New Coalition Members

While formidability and bravery are important determinants of how much individuals might contribute to their coalitions, whether or not such

contribution will be forthcoming depends on an individual's commitment to the coalitional group. For this reason, loyalty is a valued trait in coalition members. Sosis et al. (2007) argue that cultures in which coalitional conflict is important may test the commitment of male group members by subjecting them to costly rituals, such as scarification, which may involve painful treatment that leaves permanent markings. Using an ethnographic database of 60 societies, Sosis et al. (2007) found that societies that have a high frequency of warfare have costlier male-exclusive rituals. Additionally, societies that engage in external warfare (against other cultural groups) as opposed to internal warfare are more likely to have rituals that leave permanent markings, suggesting that irreversible markers of loyalty may be especially valued when the coalitional context is high stakes and temporally enduring.

The use of costly rituals has also been documented in coalitional subcultures within industrialized nations. Vigil (1996) provides an ethnographic description of gang initiation rituals that are used by Chicano gangs in California "to weed out the weak and uncommitted" (p. 151). The initiation ritual entails a violent encounter with multiple gang members, and initiates who can endure the ritual display both their toughness and their loyalty, traits that are perceived as valuable in the context of fights with rival gangs; those who are unwilling or unable to endure the initiation may be denied gang membership. Testing prospective coalition members by subjecting them to harsh ordeals is even found in the modern US military, as evidenced by the persistence of hazing rituals in the US Naval Academy. Pershing (2006) analyzed interviews with people who attended the US Naval Academy and found that most first year students (derisively referred to as "plebes") were subjected to at least moderate forms of humiliation by upperclassmen (e.g., screaming in their face) and furthermore that a majority of students approve of such moderate hazing. Indeed, a majority of students (midshipmen) agreed with a statement saying first year at the Academy "should be used to identify and eliminate midshipmen who are not committed to the Academy or cannot function effectively under pressure" (p. 481).

What all these examples of initiation rituals make clear is that coalitional entities have a keen interest in screening new members for valued traits and making the social status of coalition members contingent upon the possession of those traits. In many cases, initiation and recruitment procedures appear explicitly designed to give new coalition members a chance to signal their physical strength, their pain tolerance, their psychological fortitude in the face of danger, and their loyalty to the coalition. Insofar as initiation rituals are genuinely difficult and costly, a new member's performance is a credible signal of his ability, and a new member's willingness to endure the trial is a credible signal of his commitment to the group.

Preferences for Masculinity and Risk-Taking

Psychological studies have also tested hypotheses about how coalition-relevant traits impact partner choice among men. Winegard et al. (2016) hypothesized that men prefer to associate with masculine men because judgments of masculinity track underlying traits that are relevant to coalitional functioning, such as strength, dominance, and assertiveness. Winegard et al. (2016) conducted a series of online and laboratory studies showing that male perceivers infer that a man interested in masculine activities (e.g., sports and weight lifting) is more likely to possess aforementioned coalition-enhancing traits and is more likely to perform well as a soldier or an athletic teammate. The conclusion that masculinity is specifically valued as a cue to a man's ability to contribute to a coalition is supported by two other findings. First, while men used masculinity information to guide their choices about whom they would prefer as a basketball teammate, preferences for a masculine teammate in a poetry competition were near chance levels, suggesting that masculinity tracks traits specifically valued in domains where there is potential for aggressive coalitional activity. Second, when the sexual orientation of male targets was varied independently of their masculine interests, participants primarily relied on information about masculinity to judge

whether the target would be an effective soldier or teammate, suggesting that men desire allies who are likely to possess coalition-enhancing traits and not simply men who happen to conform to cultural norms (regarding heterosexuality, in this case). Indeed, compared to straight men with feminine interests, homosexual men with masculine interests were judged to have greater ability as a soldier and were more likely to be chosen as an athletic teammate. Similarly, Winegard et al. (2016) found that participants' expectations about the likelihood of fictional men in vignettes receiving emasculating insults from others were more strongly predicted by whether the fictional men made a sacrifice for their coalition or fled their coalition in fear than by whether the men were heterosexual or homosexual.

Given that coalitional conflict is primarily a male activity, preferences for traditionally masculine traits such as risk-taking should be sex differentiated. Farthing (2005) conducted studies with undergraduate samples to examine sex differences in preferences to associate with risk-taking individuals. Men but not women preferred same-sex individuals who took physical risks (e.g., walking down a dark alley) as friends compared to individuals who avoided physical risks. When evaluating heroic risk-takers who altruistically put themselves in danger (e.g., intervening to stop bullying), both sexes showed a greater preference for heroic friends, but this preference was stronger in men. Taken together, the findings of Winegard et al. (2016) and Farthing (2005) support the conclusion that there is a set of traits (e.g., strength, assertiveness, risk-taking), captured by traditional conceptions of masculinity, that are specifically valued by men when evaluating other men as partners and that these traits derive their value in part from their perceived usefulness in the domain of coalitional conflict.

Conclusion

Analysis of adaptive problems in the coalitional domain, such as increasing coalitional formidability and deterring free riders from obtaining coalitional benefits, sheds light on the evolutionary

origins of preferences to form groups with partners who are strong, courageous, and loyal and to avoid partners who are fearful and uncommitted. Whenever coalitional conflict is relevant, coalitional contribution appears to be culturally valued and frequently becomes directly linked with masculinity. As argued by Winegard et al. (2014), male-specific forms of social status arise not only because of intrasexual competition within groups but also due to the allocation of prestige to men who make coalitional contributions in the context of competition between groups.

Definition

Molecular structures that trigger biological reactions based on mechanical forces.

Introduction

These molecules are responsible to elicit a procedure known as mechanotransduction. Mechanical forces influence these molecules to trigger biological reactions. Eukaryotic cells contain these mechanosensory structures. There have been attempts to understand the exact functions of these molecules using a number of advanced techniques.

Mechanosensors

These are the molecules or structures that may experience a conformational change and whose interaction with other molecules is affected by mechanical forces. In some cases, the forces applied on molecules are required to trigger biologically significant reactions (Shen et al. 2017).

The mechanosensors in the cell are responsible for the process called mechanotransduction, which refers to the physiological processes through which living cells sense and respond to mechanical stimuli by converting them into electrochemical signals which consequently elicit cellular responses. Mechanosensors are molecular reporters inside the cells that connect external mechanical stimuli at the cell surface to

intracellular signaling events and downstream effectors through mechanosensory proteins (Bavi et al. 2017).

There are three main mechanosensors in eukaryotic cells: (1) those formed by the wrinkling and invagination of the plasma membrane such as caveole, microvilli, and possibly cilia; (2) intra- or extracellular elements such as the actin cytoskeleton, glycocalyx, a cadherin rich cell to cell junction; and (3) mechanosensitive (MS) ion channels, which respond rapidly to mechanical stimuli on a less than millisecond time. A combination of these could also be involved in mechanotransduction (Bavi et al. 2017).

There have been attempts to study the exact role of different mechanosensors in the literature by using magnetic nanoparticles and magnetic fields as well as a combination of other techniques – such as differentiation inducing techniques – in order to understand mechanosensory structures (Shen et al. 2017). Kita et al. (2013) have gone through a thorough description of the birth of a mechanosensor in order to comprehend as much as possible their functional properties.

Evolution Status of the Mechanosensors

Regarding the molecular evolution of mechanosensors, there have been attempts to understand the molecular basis and development of mechanosensation (Fritzsche et al. 2007). Fritzsche et al. suggest evolution of mechanosensors and evolution of auditory organs must be interpreted at the level of the changes in the receptor molecules, which mainly drive sensory evolution. Specifically, they assert that structurally different mechanosensory organs evolved in different phyla, showing a variation of a common theme quantified by a set of transcription factors in their cellular development. Also, a variety of structural designs of ion channels have been identified, which suggest that evolution of mechanosensors has taken place independently many times (Delmas and Coste 2013).

Kung (2005) has created a possible unifying principle for mechanosensation through the use of mechanosensitive ion channels. Specifically, Kung

suggested that these channel proteins sense forces from the lipid bilayer, which are also involved in opening and closing the mechanosensitive channels of animals, plant species, and fungal species.

Conclusion

These molecular structures respond to mechanical forces which consequently trigger a series of biological reactions. They are, also, involved in a process called mechanotransduction

Brain death; Cardiovascular collapse; Coma
dépassé; Deceased; Mortality

Definition

Establishing the point at which a person is considered to be dead.

Introduction

Medical progress has, somewhat paradoxically, evoked more complicated and pressing challenges as more life-sustaining technologies became available. Making determinations about death represents one such medical endeavor. In previous centuries, death was generally accepted as the complete and irreversible cessation of cardiovascular function. Over the past century, advances in the life-sustaining technology have lengthened the interval from an inciting terminal event to the point of complete cardiovascular collapse. Thus, the comparatively simple criteria of the past (e.g., protracted absence of a heart beat) have been rendered unreliable by mechanical and pharmacological support. Thus, updated criteria were required – criteria that remain somewhat controversial at the present. This entry summarizes the

legal definition of death and contrasts the cardiopulmonary criteria utilized in the past with the standardized neurological criteria of today. It concludes by highlighting some controversies surrounding the latter and juxtaposes that medical standard against religious understandings of death that frame this issue.

Main Text: Legal Definition of Death

Along with the proliferation of life-sustaining technologies, there came a need to state specific criteria for death, not only for medical purposes but also as a step in organ donation, as well as in jurisprudence, such as in criminal and civil cases. This led to the Uniform Determination of Death Act (UDDA) of 1981 (President's commission 1981) which asserts that:

An individual who has sustained either (1) irreversible cessation of circulatory and respiratory functions, or (2) irreversible cessation of all functions of the entire brain, including the brain stem is dead. A determination of death must be made in accordance with accepted medical standards.

These standards call for two separate criteria: one assessing cardiopulmonary functions and another assessing brain function. While all states utilize these criteria, some have also amended them to specify who can make such judgments or to further specify particular criteria (e.g., Oregon's version distinguishes "breathing" from "fleeting respiratory efforts or gasps"). Such amendments highlight gaps and areas lacking clarity in the 1981 statute, which often must be elaborated by states or even particular institutions. Still, the UDDA has focused attention on defining death within the cardiopulmonary and neurological paradigms.

Cardiopulmonary Criteria for Death Declaration

No formal, universally followed criteria exist for the determination of death with respect to a cardiopulmonary assessment. In practice, a waiting time

is often followed before patients are pronounced dead, which is the purview of a licensed physician. While the Institute of Medicine recommends a wait time of 5 min (Casell et al. 2000), wait times often vary among institutions. These policies aim to insure that autoresuscitation will not occur. One systematic review reported that autoresuscitation beyond 7 min has never been documented (Hornby et al. 2010). In this interval, patients are permanently dead (i.e., *will not* be resuscitated), but not irreversibly dead (i.e., *cannot* be resuscitated; Bernat et al. 2014). Bernat et al. (2014) also opined that in this context, permanent death is an appropriate surrogate for impending irreversible death. Others have argued that the use of the “permanence standard,” as indicated above, leads to a premature declaration of death (Miller and Truog 2011; Rodriguez-Arias et al. 2011). Such debates are particularly weighty in the context of organ retrieval after death declaration. Organ donation policies must balance the need for optimal organ transplantation with the adequate protection of organ donors in a manner that assures public trust in the integrity of this process.

Brain Death Criteria for Death Declaration

In contrast to the ambiguities that persist with cardiopulmonary death, specific clinical criteria were formulated for the diagnosis of brain death by the American Academy of Neurology (AAN). These criteria, first proposed in 1995, state that brain death consists of coma or unresponsiveness, absence of brain stem reflexes, and apnea (Rosenberg et al. 1995). In addition to a neurological examination, ancillary diagnostic tests such as modified electroencephalography, somatosensory evoked potentials, and brain flow studies may be useful in specific instances. A follow-up study in 2010 reported that no adult had recovered from a diagnosis of brain death rendered in accordance with the 1995 criteria. Still, considerable practice variation in brain death criteria remains evident in leading US hospitals (Wijdicks et al. 2010).

Many argue that the notion of brain death is different in important ways from other biological understandings of death, as brain dead patients are able to perform some degree of integrated functioning such as gestating a fetus, entering and completing puberty, and the maintenance of homeostatic function for some period of time (Youngner and Arnold 2001). Proponents of neurological criteria for death determination have recognized that, “more biophilosophical work remains to be accomplished to solidify the conceptual foundation of brain death to better convince skeptics why they are justified in regarding brain dead patients as dead” (Bernat 2014, p. 7).

As with cardiopulmonary death, this debate is not purely of academic interest because the demand for organs for transplantation far exceeds the supply. Certainly, the number of patients listed on transplant waiting lists has increased steadily. Currently, more than 121,000 people are awaiting transplantation in the United States (Finger 2016). Attempts to increase the donor supply have not met this escalating demand. Significant attention has been devoted to the identification of other sources of organs for transplantation, but the mainstay of organ supply still derives from deceased donors (i.e., cadaveric donation). However, moral and religious objections to organ harvesting prior to cardiovascular death continue to have an impact on organ availability.

Religious Understandings of Death

The introduction of new or unfamiliar diagnostic criteria during the dying process can amplify distress for patients or their families. Different personal and religious beliefs can be more or less compatible with scientific understandings of death. In almost all religions, there are leaders who oppose the concept of brain death, and there are leaders who see the concept of brain death as morally licit (Segal 2014). This was summarized in a 2011 editorial in the British journal, *The Lancet*, in which mainstream

views of the most commonly practiced religions generally accept the concept of brain death, whereas more fundamentalist believers tend to favor the definition in which death is constituted by the irreversible cessation of cardiovascular function (“Religion, Organ Transplantation” 2011).

Given this variety of opinion among religious scholars, lay persons may have a wide variety of beliefs. Thus, it is imperative that clinicians not assume that a patient’s belief aligns perfectly with the stance of their religious doctrine. Rather, clinicians ought to recognize that individuals often generate their own beliefs that may not necessarily align with the mainstream views of their stated religious preference, while at the same time deviating in various ways from medico-scientific criteria elaborated above. Further, it is important to recognize that some religious concepts, such as the departure of the soul from the body at death, will forever remain orthogonal to scientific determination. Regardless of scientific advancement and medical criteria, these patient values must always be considered in end of life care. In such instances, it is prudent to consult with the patient’s family members regarding the patient’s own beliefs and that patient’s view of the value of clerical input. Ultimately, however, in situations of irresolvable value conflicts, providers are typically relinquished of a duty to provide continued futile treatments for patients who meet the scientific criteria for death (particularly the neurological criteria).

Conclusion

Despite the best efforts of medical science, there is still no universal consensus on when death occurs. Religious beliefs vary from the historic definition of brain death as the irreversible cessation of cardiovascular function to those more in line with the American Academy of Neurology’s position statement. In brief, such “brain dead” patients have no evidence of neurological functioning other than the ability to sustain the circulatory system. Therefore, it is important to ascertain the patient’s beliefs through documents such as a

living will or through surrogate decision-making as codified by the governing laws.

Artificial insemination; Assisted reproduction; In vitro fertilization; Intrauterine insemination

Definitions

The use of medical technology to conceive.

Introduction

Assisted reproduction is the use of technology to attain pregnancy when traditional methods are unsuccessful. It includes procedures that have entered our vernacular including in vitro fertilization, artificial insemination, and hormonal fertility treatments. Assisted reproduction technology (ART) can help individuals experiencing difficulty conceiving or those who are experiencing infertility succeed in attaining pregnancy. Additionally, assisted reproduction can also help individuals who are hoping to conceive that have communicable viruses, such as HIV and hepatitis A or B, from giving these diseases to their partners.

The first successful use of ART occurred in 1978, when the first baby conceived from in vitro fertilization was born amidst much controversy (Al-Nuaim and Jenkins 2007). Since that time, assisted reproductive technologies have advanced greatly in terms of their ubiquity, safety, and efficacy. The Centers for Disease Control and Prevention (CDC) defines ART as all fertility treatments that handle both eggs and sperm outside of the body. This technology has significant implications for the approximate 80 million people worldwide who are estimated to be infertile, subfertile, or who suffer from viral infections

which could spread to their partner while trying to conceive (Vayena et al. 2002). However, assisted reproductive technology also presents some ethical concerns, as it increases the need for clinical research on preimplantation embryos, can result in multiple pregnancies that may be damaging psychologically and physically to both a mother and her children, and may allow parents to choose the offspring's sex or human leukocyte antigen (HLA) type (i.e., to eliminate immune issues; Pennings and De Wert 2003).

Methods of Treatment

In vitro fertilization (IVF) was the first successful ART used and is still among one of the most popular alternatives to traditional conception. This procedure involves taking both eggs and sperm and incubating them together in a petri dish outside of the body, which results in the formation of an embryo (CDC 2016). Embryos that have been successfully fertilized and are viable are then implanted into a woman's uterus. IVF begins by stimulating a woman's ovaries to produce many mature eggs at once (for an in-depth review of in vitro procedures, see Mahmoud et al. 2013). The first step of this process, known as hyperovulation, begins with pituitary down-regulation, which prevents endogenous hormones from interfering with the timing of ovulating during treatment by preventing the luteinizing hormone (LH) surge that immediately precedes ovulation. Ovarian stimulation treatments are then used to generate many healthy, developing follicles simultaneously. This is typically achieved with injections of gonadotropins extracted either from postmenopausal women's urine or through recombinant DNA technology (Mahmoud et al. 2013). This treatment continues until transvaginal ultrasounds confirm the size and number of the developing follicles are sufficient for extraction.

Once the oocytes are developed enough to be used for IVF, human chorionic gonadotropin (HCG) is injected to mimic the LH surge, which begins the final oocyte maturation process. These mature oocytes are then retrieved from the ovary using a needle attached to the transvaginal probe which aspirates the developed follicles from the

ovary. The oocytes are then incubated with sperm retrieved from the male partner together on special petri plates and monitored for normal development. If normally developing embryos are available after 5–6 days, then up to two (or four, depending on the country) are selected to be transferred back to the woman's uterus to further develop.

There are many other expansive procedures used to combat infertility that are concomitant with IVF that can be used to counter more specific infertility issues. For example, when the source of a couple's infertility is due to abnormal sperm characteristics (male-factor infertility), intracytoplasmic sperm injection (ICSI) in tandem with IVF can help couples conceive over IVF alone (Van Steirteghem et al. 1993). ICSI takes a single spermatozoon and injects it directly into the cytoplasm of an oocyte, which can compensate for structural problems with a man's sperm that may otherwise prevent it from fertilizing an egg (Palermo et al. 1992). If someone is experiencing complete infertility, meaning it is impossible for them to conceive, it is also possible to seek a third party donor to help conceive. In this case, viable sperm may be used from a donor to fertilize the woman's egg, or an oocyte from another woman may be fertilized with the man's sperm via IVF and implanted in the woman. Surrogacy, wherein a woman agrees to carry a pregnancy to term for another couple, is another form of third party ART. This is especially the case when a woman desiring a child cannot safely carry a pregnancy to term, has a congenital defect that has caused the absence of necessary reproductive organs, or does not have fertile eggs (Esfandiari et al. 2003; Goldfarb et al. 2000).

Although IVF is the most effective and most common form of ART (CDC 2016), there are other techniques that are still used, including intrauterine insemination (IUI), gamete intrafallopian transfer (GIFT), and zygote intrafallopian transfer (ZIFT) (Custers et al., 2011). IUI is the injection of prepared sperm into the uterus and is sometimes accompanied by mild or moderate superovulation induction. IUI can be performed during a woman's natural cycle and with fewer possible medical complications than IVF, making

it a safer and cheaper alternative (Goverde et al. 2000). However, whether or not IUI is as effective as IVF is unclear, and in recent years, IVF has provided the highest rate of pregnancy in the United States (Van Voorhis 2006). GIFT and ZIFT are less frequently used methods (about 1% of ART cycles) wherein a laparoscopy is performed and either sperm and an unfertilized eggs or a zygote is transferred to a fallopian tube (Van Voorhis 2006). These procedures have become less common over time because of the risks associated with laparoscopies.

Why Use Medically Assisted Reproductive Technology?

One of the main reasons to use ART is when an individual is experiencing infertility. The CDC (2016) defines infertility as the inability to conceive after 1 year of having unprotected sex, and both men and women can experience infertility. Causes of infertility in women include ovulation disorders, damage to the fallopian tubes, bilateral tubal occlusion (BTO), genital tract disorders, endometriosis, and gonadal dysgenesis (Hull et al. 1985), whereas in men infertility can be caused by seminal defects such as azoospermia (the absence of sperm in semen), oligozoospermia (low sperm number), and asthenozoospermia (poor sperm locomotion; Thonneau et al. 1991). Although both men and women can experience infertility or subfertility, there are fewer treatments that are successful in treating male infertility (Hull et al. 1985; Jungwirth et al. 2012).

As noted above, individuals may also use ART to avoid spreading a disease that could be sexually transmitted to a partner while attempting to conceive. Semen has been shown to carry infection from donor to recipient in the absence of any other sexual contact (Araneta et al. 1995). To prevent the male-to-female spread of a disease in a couple which have different serotypes, some teams have used assisted reproduction technologies such as intrauterine insemination and in vitro fertilization in combination with sperm washing techniques that remove all seminal plasma away from sperm (so that only spermatozoa remain) to help couples successfully conceive and give birth to children without partner contamination (Englert et al. 2004).

A less common and more controversial purpose for using ART is to allow couples to conceive a child of a specific sex to avoid having a child with a deleterious sex-linked disease. For example, consider a woman who is a carrier for a recessive X-linked disorder, such as Duchenne muscular dystrophy (DMD), which causes muscle degeneration and eventually premature death. For a female to express this disorder, she must have two X chromosomes carrying the recessive allele, and for a male to express the disorder, he must have only one X chromosome carrying the recessive allele. The chances that any of her female offspring will inherit the X chromosome carrying the recessive allele are 50%. This means that there is a 50% chance that her female offspring will be carriers of the disease. Her male children, on the other hand, who will receive their Y chromosome from their father and their X chromosome from their mother, have a 50% chance of having DMD. To avoid the chance of having a male child who has DMD, it is possible to selectively fertilize the woman's eggs with sperm carrying an X chromosome to ensure the birth of a daughter. Using flow cytometry, sperm samples can be separated based on mass because sperm carrying an X chromosome are slightly heavier than sperm carrying a Y chromosome (Garner et al. 2013). This enables medical professionals to choose sperm with which to fertilize the mother's eggs to greatly increase the likelihood of her giving birth to a daughter (Karabinus et al. 2014).

Finally, it is also possible to use ARTs in combination with a preimplantation genetic diagnosis (PGD) to select embryos with specific human leukocyte antigen (HLA) makeups for the purpose of conceiving a child who may act as a donor sibling for a child affected by a bone marrow disorder in need of a stem cell transplantation (Verlinsky et al. 2004). This approach can be used to help individuals suffering from a number of diseases which can be treated by a bone marrow transplant in the absence of an existing HLA-matched donor. In these cases, PGD is used to take a single cell from an embryo created via in vitro fertilization and test this cell for the absence of the disease the existing child has and the desired HLA match to the sibling (Rechitsky

et al. 2004). If the embryo has the correct HLA alleles and does not have the gene causing the disorder, it is chosen to be implanted in the uterus and can result in a child who may act as a stem cell donor for their sibling.

Risks Associated with ART

Although ART treatments are becoming much more frequently used for the treatment of infertility, there are some possible risks associated with undergoing IVF and other ART treatments. These include risks to the mother such as ovarian hyperstimulation syndrome (OHSS) and multiple pregnancies and risks to the newborn such as an increased chance of birth defects and increased risk of low birth weight compared to spontaneously conceived infants. OHSS is caused by using gonadotropins and other agents to stimulate ovulation during fertility treatments. It causes the ovaries to increase in size, which causes abdominal pain, and, in more advanced forms, can cause the ovaries to become cystic, negatively impact the cardiovascular and renal system, and impair diaphragm movement and breathing (Delvigne and Rozenberg 2003). Although fatal cases are rare, it is important for physicians to monitor patients undergoing hormonal fertility treatments to manage any symptoms of OHSS. Another risk of ART treatments is that women have an increased chance of a higher-order pregnancy, meaning that they are more likely to deliver multiple babies from the same gestation (twins, triplets, etc.). This is because during most ART treatments, multiple embryos may be transferred back to the woman to increase the chance of a successful pregnancy (ESHRE Capri Workshop Group 2000). A multiple gestation pregnancy increases risk of medical complications for both mother and infants, increases economic costs of pregnancy, and can also have negative social and psychological impacts on the mother and father (Pennings and De Wert 2003). Recent advances in single embryo transfer (SET) IVF have, however, been able to lower the instance of multiple gestations while still providing a comparable pregnancy rate (Forman et al. 2013).

Multiple pregnancies not only have an impact on the mother; they also increase the likelihood

that a child will be born underweight. Interestingly, in a study including 42,463 infants conceived through ART, Schieve et al. (2002) found that twins conceived from ART were no more likely to be underweight than twins from a spontaneous conception. However, they found that singletons born after 37 weeks of gestation had a 2.6 times higher chance of being underweight than the general population, which was not explained by differences between the population of women who conceive spontaneously and those who conceived via ART. The authors cautiously suggest that some aspect of the ART treatment and/or hormonal fertility treatment is associated with birth defects, although more research in this area is required. In addition to increased chance of low birth weight, it also appears that ART treatments increase the risk of a child being born with a birth defect (Hansen et al. 2002, 2005). Davies et al. (2012) found that ART treatments were associated with a significantly increased risk of cardiovascular, musculoskeletal, urogenital, and gastrointestinal defects and cerebral palsy in infants conceived through ART techniques compared to infants which were spontaneously conceived.

Ethical Concerns

As with other topics related to reproduction, ART treatments have historically been surrounded by ethical intrigue and concern. Some of the prominent concerns have to do with the excess embryos created during IVF and the use of preimplantation genetic diagnosis (PGD) to select for desired embryos.

ART treatments are closely associated with research on preimplantation embryos, and embryos that are not used during an IVF cycle or chosen to be used at a later time can be donated for research. The center of this ethical debate is whether or not embryos have the same rights and moral status as children or adults (Pennings and De Wert 2003). From one perspective, embryos are “nonpersons,” and therefore research performed on them should be morally indifferent and depend only on the inclination of the gamete donors (Chervenak and McCullough 1997). On the other hand, some feel that personhood begins

at fertilization and the potentiality of the embryo to develop into a person means that these embryos should be treated with the moral status and respect of a child or an adult (Pennings and De Wert 2003).

Another controversial aspect of ART is the relatively recent ability to genetically screen potential embryos before implantation and select embryos that are most likely to produce healthy pregnancies. One consequence of PGD is that parents are now able to prescreen embryos to avoid the appearance of a sex-linked disorder by selecting the sex of their child. Although PGD is used for medical sex selection and is done with the intent of improving the life of a potential child, it may also be used as a non-medical, social sex selection mechanism (Pennings and De Wert 2003). In countries with more lax regulations or less enforced restrictions on PGD and ART treatments, individuals may take advantage of technology for social sex selection; when there are limitations on the number of children couples are allowed to have and where the birth of one sex is favored over the birth of another, couples may elect to use PDG to select the sex of their child (Whittaker 2011).

Conclusions

Since the first child born through IVF conception in 1978, ART treatments have become more ubiquitous, more socially acceptable, safer, and more efficacious. However, treatments like IVF still face challenges in developed countries like the United States. The financial burden of ART prevents lower-income individuals from accessing treatment, and there is still discrimination against women of older age, poor individuals, lesbians, and single women (Peterson 2005). Additionally, access to ART differs greatly across the globe, and laws regulating the use of ART are inconsistent within and between countries. Although legislation may need to keep pace with innovation, continuing ART advances offer hope to a large portion of the world's population who struggle to conceive.

Members of Coalition Must Believe They Will Win

Adam Tratner
Oakland University, Rochester, MI, USA

Synonyms

[Intrasexual competition](#); [Male warrior psychology](#); [Risk contract of war](#)

Definitions

Throughout human history, participating in warfare afforded potential benefits for involved coalitions of males, but also bore a risk of injury or death. Males may have evolved psychological mechanisms that compute the risks associated with intergroup violence, are sensitive to strategic imbalances, and motivate participation when victory seems highly probable. Therefore, coalition members' willingness to participate in warfare rests on whether they believe that they will win.

Introduction

Over the course of human evolutionary history, engaging in warfare with other groups allowed men to expand their territory, acquire new hunting and foraging grounds, and obtain additional mating opportunities (Wrangham 1999; Wrangham and Glowacki 2012). Men could forge coalitions with other male group members to gain access to female members of other groups, by eliminating coalitions of rival males and/or capturing outgroup women. Warfare also presented males with the opportunity to gain additional resources and social status, thereby increasing one's ingroup mating appeal (Buss 1998). Males therefore stood to gain substantive reproductive benefits from strategic participation in intergroup conflict, prompting scholars to propose that men possess an evolved *male warrior psychology* (McDonald et al. 2012; Van Vugt et al. 2007). This male warrior psychology is thought to encourage warfare when it can be carried out with a strategic advantage, because warfare is inherently dangerous for involved individuals.

Strategic Considerations in Warfare

Though there are benefits to be reaped from intergroup conflict, warfare confers an elevated risk of injury or death for participants. Thus, evolution would not have favored individuals, or more specifically, genes, that engaged in frequent, gratuitous violence. However, it is likely that

evolution favored genes that built individuals who engaged in intergroup violence opportunistically, and who can identify as well as take advantage of situations where victory seemed assured (Tooby and Cosmides 1988; Wrangham 1999). Due to the inherent risk of losing one's life (or limbs), natural selection likely favored traits in males that promote warfare when enacted in a way that reduces the risk of injury or death, prompting the evolution of psychological characteristics that encourage participation in warfare when the probability of victory is high. If, for example, a coalition perceives a significant tactical advantage (e.g., opponents outnumbered, unprepared), and the risk of injury or death is perceived to be both small and randomly distributed among participants, then coalition members may be incentivized to engage in warfare (Johnson and MacKay 2015; Tooby and Cosmides 1988; Wrangham 1999). Hence, the male warrior psychology may consist of psychological mechanisms that compute the risks and benefits associated with participation in warfare, and encourage violence when the perceived probability of success is high.

Victory must be Assured

Inferring from modern hunter-gatherers, the dominant style of combat for ancestral humans likely took the form of asymmetric raids in which a male coalition of individuals surround and attack a small subset of rival group members, therefore resulting in a high probability of success in battle (Johnson and MacKay 2015; Wrangham 1999; Wrangham and Glowacki 2012). Modern hunter-gatherers mostly carry out attacks on rival groups when coalitions have a clear strategic advantage, such as possessing superior numbers and the element of surprise (Wrangham and Peterson 1996; Wrangham 1999). This style of combat is structured to reduce potential costs (e.g., casualties), and, as a result, attackers rarely suffer fatalities during such violent encounters (Wrangham and Glowacki 2012). If warfare was not carried out in a strategic manner (e.g., no tactical advantages, equal or lesser fighting strength than opponents) then participants might incur immense fitness

costs (e.g., injury or death). Therefore, to prevent those potential costs, males likely evolved a toolkit of psychological mechanisms that motivate warfare only under certain conditions, particularly when victory is assured. Given this, the willingness of coalition members to engage in warfare is contingent on having significant strategic advantages over ones opponents, and also the perception that such advantages are present.

Thus, certain factors that alter the perceived likelihood of victory may increase the motivation for coalition members to engage in warfare. For example, social inputs (e.g., political ideology) may manipulate male warrior psychological mechanisms to encourage participation in warfare by exaggerating the perceived likelihood of achieving victory. This may be achieved by downplaying the dangerousness, group size, and fighting ability of rival coalitions. Convincing coalition members of their ethnic and cultural superiority, or their prowess as warriors, may facilitate warfare against groups perceived to be weak, inferior, or tactically disadvantaged.

Conclusion

Participation in warfare presented ancestral men with potential benefits, such as additional mating opportunities, but also an increased risk of injury or death. Thus, men have evolved psychological adaptations that promote strategic participation in warfare, and facilitate involvement on behalf of coalition members when the perceived chance of victory is high. This includes psychological mechanisms that are sensitive to information about the group size and formidability of rival coalitions, identifying situations where there is a significant strategic advantage, and motivating participation in warfare when coalitions believe that they will win.

[Replicating entities of culture](#); [Unit of cultural transmission](#); [Unit of imitation](#)

Definition

Replicating entity able of being transmitted culturally.

Introduction

In 1976, Richard Dawkins published the book *The Selfish Gene*. In its first ten chapters, the author

brings an explanation over evolutionary thoughts, focusing exclusively on genes as units of replication. Only in the last chapter, Dawkins exposes the concept of *memes*, emphasizing its existence as another kind of replicator and showing that genes are not the only components of this class. In this context, exploring the idea of *meme*, the author starts from a notion of culture as a human peculiarity that differs *Homo sapiens* from the others species, passing through the inauguration of the idea of *memes* and then explaining the manner by which *memes* can replicate themselves.

What Is Unusual About Man

According to Dawkins (2006), the human species can be considered unique because of its ability of promoting culture. For him, although cultural transmission is not a characteristic present only in man, it is in this species that cultural evolution proves to be more powerful. Language, fashion, and art are examples of culture in the human species, being transmitted much faster than genetic transmission. Dawkins (2006) argues that cultural transmission, even though it is analogous to genetic transmission, once both can generate a type of evolution, occurs in an accelerated manner.

The New Replicators

Blackmore (2001) predicate that when *memes* arose, everything changed in evolution. In the same way, Dawkins (2006) affirms that, even if the emergence of the new replicator is recent, they are promoting evolutionary changes quite rapidly, surpassing the genes.

A replicator is defined by Dawkins (1976) as an information unit capable of being reproduced with some variations or errors. As discussed earlier in *The Selfish Gene*, Dawkins inaugurates the concept of *memes* as new replicators, disregarding the idea that genes would be the only replicators on the planet. In this sense, *memes* are, at the same time, cultural phenomena and living structures capable of self-replicating, being transmitted from brain to brain (Jarzewicz 2016).

In this way, a *meme* is considered by Dawkins as a unit of cultural transmission (Ambrus 2017). For example, *memes* may refer to melodies, dance steps, and thoughts (Ambrus 2017) or to clothing fashions, customs, and ceremonies (Dawkins 2006).

Discussing over how to distinguish a meme's unit, Dawkins (2006) suggests the existence of large and small units and "units within units." As an example, Dawkins affirms that a tune is one meme, but the whole Beethoven's ninth symphony is also a meme. However, the author implies that a memorable excerpt from the symphony which has become more famous than the rest of the composition deserves to be called a meme.

Survival Value and How Memes Can Replicate

Dawkins (2006) proposes a reflection on why do some ideas have high survival value. The concept of survival value, as the author explains, is related with the stability and the penetrance that some ideas have in the cultural environment. As an example, he brings the ancient and widespread idea of God, replicated over several generations by the spoken and written word, having great music and great art as allies. Dawkins considers that the survival value of the god meme results from its great psychological appeal.

As postulated by Dawkins (2006), *imitation* is the manner by which *memes* can replicate themselves. Therefore, the author explains that, in general, *longevity*, *fecundity*, and *copying-fidelity* are the qualities which define the high survival value of a meme. According to Blackmore (1999), those three words brought by Dawkins mean that, in the process of imitation, the replicator needs to have long-lasting, numerous, and accurate copies. In other words, as suggested by Jarzewicz (2016), while explaining the idea of Dawkins, the three conditions a successful meme must fulfill are lifetime, by which a meme has to survive as long as possible; productivity, by which a meme must be copied as much as possible; and reliability, by which the copies of a meme have to be precise.

Conclusion

In the final considerations of this entry, it is relevant to point out that Dawkins (2006) designates as a remarkable quality of memes their potential of perpetuation in time. The genes' potential, in general, is far more limited than memes' influence over the generations. While the contribution of genes dissolves as each generation passes, when a person contributes to the cultural development with an idea, a music, or a poem, it may live on for countless years. As examples of long-lasting cultural contributions, Dawkins exposes the meme complexes of Socrates, Leonardo Da Vinci, Copernicus, and Marconi.

In addition, considering it as a "serious point," Dawkins (2006) highlights that the evolution of cultural traits may happen with the only purpose of being beneficial to itself. The author's conclusion leads to the perception that, for the analysis of the survival values of memes – like religion, music, and ritual dancing – the conventional biological survival values do not have to be the focus, despite they may also be present. Therefore, Dawkins (2006) understands that memes started to take over automatically in the moment that genes provided brains capable of rapid imitations, with no need of genetic advantages in the process.

Even though the memes replicate themselves in a selfish, compulsive, and potentially harmful way to mankind, Dawkins suggests two unique qualities of man capable of overcome this matter: the capacity for conscious foresight – the ability of imagining the future – and the capacity for genuine altruism. Those particularities, combined, may represent a tool with which humanity can turn against the blind replicators, or as the author states: "We are built as gene machines and cultured as meme machines, but we have the power to turn against our creators" (Dawkins 2006, p. 201).

Memory Enhanced for Cheaters Versus Non-cheaters

Raoul Bell and Axel Buchner
Heinrich Heine University Düsseldorf,
Düsseldorf, Germany

Synonyms

[Cheater memory advantage](#); [Memory for reputations](#); [Reputational memory](#); [Social source memory](#); [Source memory advantage for faces of cheaters](#)

Definition

Enhanced memory for the association between a face and cheating behavior in comparison to the association between a face and trustworthy or neutral behavior.

Introduction

Assumptions about memory are an important component of models of reciprocal cooperation. This can be exemplified using the well-known tit-for-tat strategy, which consists of (a) cooperating on the first move in a prisoner's dilemma game and (b) then mirroring the partner's behavior in the next round of the game. This strategy obviously implies that people are able to remember specific instances of cooperation or defection. All models of direct reciprocity require that the previous history of interactions is remembered to some extent. Increasingly complex strategies make increasing demands on memory. Models of indirect reciprocity often imply that reputational information about third parties is shared and remembered. If assumptions about memory that are implied by a model are unrealistic, the model is likely to be inadequate. Therefore, assumptions about memory for social interactions have to be tested because they have important implications for the evolution and stability of cooperation.

Enhanced Memory for Faces of Cheaters?

A popular assumption in evolutionary psychology is that cheaters should be preferentially remembered (Mealey et al. 1996). This hypothesis can be derived from specific models of human cooperation such as tit for tat. These models imply that cooperation is the norm and cheating is the exception. Good memory for cheaters is essential because individuals with a preference for reciprocal cooperation have to know when to switch to defection. One study (Mealey et al. 1996) has found results that were interpreted as evidence for a recognition advantage for faces of cheaters.

However, this finding could not be replicated in follow-up studies (e.g., Buchner et al. 2009). Instead, face recognition was not affected by whether persons were described as cheaters, trustworthy, or neutral persons. This is neither surprising nor problematic from a functional point of view. Only recognizing a face as familiar does not help to avoid cheaters in social exchange if the cheating context is not remembered as well. Increased familiarity without context or source memory may even lead to enhanced, not decreased, trust. It is therefore theoretically much more important that source memory, but not recognition, was found to be enhanced for faces of cheaters in comparison to those of trustworthy or irrelevant persons (Buchner et al. 2009).

Why Is Source Memory for Cheaters Enhanced?

One way to explain the source memory advantage for faces of cheaters is to assume that people have a specialized module for remembering cheaters. However, given that cheating elicits strong negative emotions, a plausible alternative is that these negative emotions are responsible for the memory advantage. Bell et al. (2014) have observed that people are more likely to remember the immorality of cheating behavior when they have suffered from it than when they have benefitted from it. This may suggest that the source memory advantage is mediated by negative arousal. However, it turned out that another factor is even more important: the degree to which the cheating behavior violates expectations. Cheating is, per definition, a violation of social norms and, therefore, behavior that can be considered unusual and unexpected in most social contexts. This opens the possibility that the source memory advantage for cheating behaviors is, in fact, due to the violation of expectations.

Many results have confirmed that expectancy violations play an important role in explaining the source memory advantage for cheaters. One of the most important findings is that the cheater advantage is restricted to situations in which there is a strong norm for cooperation. For instance, there is a robust source memory advantage for faces of

cheaters when vignettes are used that describe real-world norm violations such as the selling of military weapons to criminals (Buchner et al. 2009). However, the effect disappears when the vignettes describe more common cheating behaviors such as using unlicensed computer programs, which are less negatively evaluated by the majority of the participants (Bell and Buchner 2011). The influence of the relative frequency of cheating and cooperation has been directly examined in social dilemma games. Bell et al. (2010) examined memory for the partners' behaviors in a sequential prisoner's dilemma game. When the majority of the partners in the game were cooperative, participants were more likely to guess that an unknown partner was trustworthy, but memory was better for a partner's cheating than for a partner's cooperation. However, when most of the partners were cheaters, the opposite pattern emerged: participants were more likely to guess that an unknown partner was a cheater, but their memory was better for their partners' cooperation. When the participants encountered an equal proportion of cheating and cooperating partners, they remembered their partners' cheating and cooperation equally well. Similar results have been obtained in a trust game (Barclay 2008). These results suggest that people's memory for cheaters and cooperators is quite flexible. Source memory is not always enhanced for negatively arousing information, but is instead better for information that violates expectations.

These findings are inconsistent with the assumption of a specialized module for remembering cheaters. However, it stands to reason that the flexible and fairly general expectancy-violation mechanism identified by this research is much more compatible with a functional perspective on cognition than a cheater recognition module. First, it is important to realize that people do not have perfect knowledge about social interaction partners because (a) they may not know the person or (b) they may have forgotten the previous interaction because memory is error prone. When uncertain about another person's past behaviors, people may use other information that is available to them to guess the person's character traits, such as the prevalence of cheating or cooperation in the

population (Barclay 2008; Bell et al. 2010) or the person's facial appearance (Bell et al. 2012b), and adjust their own behavior accordingly. Second, a functional perspective suggests that we should not waste our precious memory resources. In a social environment in which the majority of the partners are untrustworthy, it would put a large burden on memory to remember all of them, and it would be more efficient to focus on the few cooperative individuals with whom relationships of trust and cooperation are possible. In an environment in which the majority is cooperative, it makes sense to focus on the few cheaters to avoid trusting them. This ensures that memory resources are not wasted at encoding, and it also ensures that the relevant information can be efficiently retrieved.

The above model is in line with how schema theories account for schema effects on memory in general. For instance, the schema-plus-tag model (Graesser and Nakamura 1982) predicts that the memory trace of an event consists of (a) a pointer to a schema (e.g., about socially appropriate behavior) and (b) tags for bits of information that do not fit into the schema. A tag is only constructed for atypical items such as socially inappropriate or exceptional behaviors. When memory is expressed in terms of memory sensitivity and is, therefore, adjusted for guessing, memory for typical behaviors is often found to be poor because the typical information is produced at test whether it was present at encoding or not. This is exactly the pattern of findings observed in the literature on cheater memory described above. The schema-plus-tag model implies that the memory advantage for the atypical information is based on simple, unelaborated tags. In consequence, atypical information can be robustly encoded even under conditions of depleted cognitive resources (Graesser and Nakamura 1982). In line with this idea, it has been shown that people do not remember the details of the episodes that have led to the classification of a person as a "cheater," but are able to differentiate between contexts that necessitate different types of avoidance reactions, such as immoral and disgusting behaviors (Bell et al. 2012a). Emotional tagging thus integrates the relevant information into a summary judgment that can be quickly

retrieved and may allow for fast decisions in complex and stressful situations.

Of course, the efficiency of this strategy is not restricted to memory for cheaters. Instead, this strategy is generally a simple and frugal way to encode and remember schema-atypical information. Unsurprisingly, it can be shown that the same strategy is used to encode and to retrieve information about other types of items and contexts (Mieth et al. 2016). Thus, a very simple mechanism is able to solve the problem of how to remember efficiently the information that is either (a) consistent with prevailing schematic knowledge and, therefore, expected or (b) inconsistent with prevailing schematic knowledge and, therefore, unexpected. This mechanism presumably provides useful input for a wide range of problems, such as avoiding cheaters in social exchange (Barclay 2008; Bell et al. 2010, 2012b) or avoiding the consumption of spoiled food (Mieth et al. 2016).

Conclusion

Source memory, not old-new recognition, is enhanced for faces of cheaters (Buchner et al. 2009). However, this source memory advantage for cheaters depends on participants' expectations and disappears when people expect to be cheated (Barclay 2008; Bell et al. 2010, 2012b). These findings suggest that it is not the negative arousal associated with cheating but the unexpected nature of the norm violation that is primarily responsible for the memory advantage. From a functional perspective, it generally seems to be a highly efficient and frugal strategy to rely on schematic knowledge to guess information that cannot be remembered and to preferentially attend to information that cannot be inferred from these existing schemas.

Men but Not Women Will Have Adaptations for War

Adam Tratner

Oakland University, Rochester, MI, USA

Synonyms

[Intrasexual competition](#); [Male warrior psychology](#)

Definition

Adaptations that promote warfare are present in men and not women because males stood to gain substantive reproductive benefits from strategic participation in warfare over the course of human evolution. This resulted in the selection of traits that assist the formation of warrior coalitions, galvanize hostility toward outgroup members, and identify of situations where warfare can be carried out strategically.

Introduction

Both past and present, warfare between groups is by and large orchestrated and carried out by men (Goldstein 2001; Wrangham and Peterson 1996). This propensity for men (as opposed to women) to engage in warfare has its roots in the processes of sexual selection.

Sexual Selection

In most species, male reproductive fitness is limited by access to fertile females. Upon reaching

physical maturity, males produce gametes (i.e., sperm) in large quantities for the majority of their adult lives and do not gestate offspring in utero. Males are therefore capable of reproducing throughout much of their lifespan and can sire offspring with multiple females simultaneously. For males, the costs associated with conceiving offspring are relatively low, as it requires only the time, energy, and effort necessary to produce an ejaculate and mate. In contrast, females produce significantly fewer gametes (i.e., ova), are limited in the number of offspring they can conceive at any given time, and incur immense physiological costs carrying and caring for offspring, which in turn mitigates the amount of time and effort that can be devoted to mating (Trivers 1972). This results in a reproductive asymmetry, such that males can potentially produce significantly more offspring than females over the course of their lifespans.

Because males have fewer limits placed on their reproductive capacity, they can continuously seek out mating opportunities. Males may enhance their fitness by monopolizing reproductive access to numerous females. Females, however, do not profit to the same extent from increased access to viable mates given their lower reproductive ceiling. This asymmetry results in notable sex differences in within-sex variability in reproductive success; variance in women's reproductive success is quite low, whereas reproductive success varies considerably for men. For example, some males are hyper-successful (i.e., achieving disproportionately higher number of mating opportunities or access to higher quality mates), while others produce no offspring at all. This disparity in reproductive success outcomes is a consequence of *intrasexual competition* between males.

Intrasexual Competition and the Antecedents of Warlike Behaviors in Men

Intrasexual competition is defined as competition that occurs between members of the same sex for mating opportunities with members of the opposite sex. Intrasexual competition induces

relatively strong selection pressure on traits that assist in competition for mates. These pressures are the precursor to sex differences in size, strength, aggression, and even warlike behaviors observed in males across species, as possessing these traits allows males to optimally engage in intrasexual competition (Geary 2010; Trivers 1972). Intrasexual competition usually entails males competing with one another for access to females, and this pattern rarely occurs in reverse (Trivers 1972). This is in part due to the fact that females stand to gain fewer benefits from participation in intrasexual competition, and also incur greater fitness costs relative to males (Campbell 1999). For most species, and humans in particular, females are essential to offspring survival (Sear and Mace 2008). Thus, for females, engaging in high-risk strategies (e.g., physical aggression) to compete for the “best” mate more acutely impacts their ability to procreate and ensure offspring survival. As a result, females more often engage in indirect intrasexual competition (e.g., gossip) to devalue their same-sex rivals, and therefore optimize their mating opportunities (Campbell 1999). This allows females to engage in intrasexual competition with a significantly reduced risk of injury.

Males, however, must compete rigorously with one another or risk losing mating opportunities. This may take the form of direct competition for mating opportunities (i.e., through displays and/or violence), or indirectly through competition for the acquisition of tangible or nontangible resources, such as dominance and social status within a group. These competitive strategies need not be mutually exclusive, and the latter can readily translate to mating opportunities, because females are more likely and willing to provide mating access to those individuals who display high status within a group (Buss 1998). Therefore, males stand to gain from engaging in high-risk intrasexual competition because it provides men with the potential for greater mating opportunities.

Warfare: A Male Affair

Intrasexual competition among males is not restricted to mating contests within a given

group, but also extends to conflicts with other groups. Engaging in warfare with other groups can similarly increase one's access to direct and indirect reproductive resources. Males may form coalitions with other male group members to obtain mating opportunities with female members of other groups, and eliminate rival males from other groups. Involved individuals may acquire both tangible and intangible reproductive resources, such as direct mating opportunities with outgroup women, as well as greater resource access and social status within one's group, which may increase one's mating appeal. Therefore, males in particular can reap substantive benefits from strategic participation in warfare. Because males stood to gain substantive reproductive benefits from strategic participation in warfare over the course of human evolution, adaptations that promote warfare are present in men but not women.

There are several hypothesized adaptations for warfare that men may possess. For example, men possess a greater proclivity for forming cohesive coalitions of group members (Tooby and Cosmides 1988). Men display greater ingroup favoritism, and are more discriminating and hostile toward outgroup members (Navarrete et al. 2010). Furthermore, men exhibit a greater preference for group-based hierarchies than women, and have a greater desire to establish, maintain and justify dominant–subordinate relationships among social groups (Lee et al. 2011). In addition, men may possess psychological mechanisms that compute the risks and benefits associated with participation in warfare, prompting violence when the probability of victory is high (Tooby and Cosmides 1988). This includes psychological mechanisms that are sensitive to information about the group size and formidability of one's opponents.

Conclusion

Sex differences in minimal parental investment result in reproductive asymmetries between men and women, such that men have a higher reproductive ceiling than women. Because men have a greater reproductive capacity, they can

continuously seek out mating opportunities, leading to intrasexual competition among men for mating opportunities with women. Intrasexual competition induces strong selection pressures on the development of traits such as increased size, strength, and aggression – traits that enable greater success in intrasexual competition. As a result, men evolved the capacity to engage in violent, high-risk intrasexual competition to obtain mating opportunities. Such violence can extend beyond one's social group to other social groups, allowing men to gain access to women in other groups, while increasing their mating appeal within their own group. Thus, men have adaptations for warfare because strategic participation in warfare increased their reproductive fitness over the course of human evolutionary history.

Men in Positions of Power

Gregg R. Murray
Department of Social Sciences, Augusta
University, Augusta, GA, USA

Synonyms

[Dominance](#); [Leadership](#); [Social authority](#); [Social rank](#); [Social status](#); [Status hierarchy](#)

Definition

An individual or group possesses *power* when holding “asymmetrical control” over valued resources, while an individual or group possesses *status* when having “social prestige” and respect (Fiske et al. 2016, p. 11). Although conceptually distinct, power and status tend to be correlated. In this entry, “male” and “female” indicate biological characteristics and not characteristics of psychological or social identity.

Introduction

Humans are highly social animals. Many scholars argue this characteristic is the result of the advantages in survival and reproduction that humans and other social species gain when individuals band together into groups (e.g., Kenrick et al. 2010). Further, groups with hierarchies tend to gain more evolutionary advantages than egalitarian groups (e.g., van Vugt 2006). In particular, a key feature of social hierarchies is that high-ranking members tend to coordinate their group’s efforts to resolve recurring challenges as well as to

deter and punish members who benefit from the group’s efforts without contributing to them (i.e., free riding). To coordinate a group’s efforts, higher-ranking members usually disproportionately control resources and influence over other members, that is, they hold asymmetrical control over valued resources and others, which is otherwise known as power (Fiske et al. 2016). Consistent with research supporting an evolutionary basis for social hierarchies, evidence is beginning to emerge of an indirect genetic contribution to social hierarchy formation, possibly through expressions of behaviors such as social dominance that are related to support for such social structures (van der Kooij and Sandi 2015).

Male dominance in social organizations has been long recognized. Cross-disciplinary research in diverse fields such as nonhuman animal behavior, anthropology, economics, and psychology documents a direct relationship between biological sex and leadership across time, cultures, and species, suggesting that such dominance may be influenced by evolutionary factors and not only by social construction. With few exceptions (e.g., killer whales, lions, spotted hyenas, bonobos, lemurs, and elephants), male group dominance is nearly universal in primate and mammalian animal groups. Specifically in humans, the relationship is documented going back as far as Egyptian pharaohs; Chinese, Japanese, and Roman emperors; Catholic Popes; and European monarchs (Murray and Murray 2011). The current situation in the political and business domains has not nearly come to parity between the sexes. For example, female leaders represent less than 10% of leaders of UN member states (Geiger and Kent 2017) and of chief executive officers of Fortune 500 corporations (Pew Research Center 2018).

Why Male Dominance?

This question can be evaluated from a demand-supply perspective. That is, there may be a greater demand from followers for male leaders, and/or there may be a greater supply of potential candidates for leadership who are male. In terms of demand, gender stereotyping, role congruity, and

social role theories, all widely supported hypotheses, suggest that consequential leadership traits are primarily associated with males, which makes it more difficult for females to be evaluated positively as leaders (e.g., Eagly et al. 2019). Other research adds that leadership is situational such that male leaders are preferred in some contexts and females in others (van Vugt and Spisak 2008), possibly as a result of evolutionary concerns related to intergroup threat (Murray and Carroll 2019).

In terms of supply, higher-ranking group members gain access to more group resources, have fewer constraints imposed on them, and reproduce more efficiently. While these advantages appeal to both males and females, psychological research suggests that males tend to be more hierarchical socially, as demonstrated by greater social dominance orientation (e.g., Lee et al. 2011), and more motivated than females to lead in hierarchical settings (Fiske and Berdahl 2007). They are also more likely to consider the potential for gaining power in decisions related to leadership and its attainment (Hernandez Bark et al. 2016). Further, widespread gender stereotyping may demotivate females from aspiring to leadership positions as a result of social hurdles faced or self-stereotyping into non-leadership roles. In addition to these psychological factors, evidence suggests that biological factors may also play a role in males disproportionately attaining positions of power. For instance, the hormone testosterone, which males possess at much higher levels than females, has been associated with leadership attainment via dominance, influence-seeking, and risk-taking behaviors (Antonakis 2011).

Does Male Dominance Matter?

There is substantial evidence that the sex of the person in power is consequential to performance and outcomes. For instance, in political governance, female legislators tend to deliver more financial benefits to their constituents and to sponsor more legislation (Anzia and Berry 2011). In the business domain, evidence suggests that increased numbers of female corporate board

members are related to outcomes such as fewer workforce reductions and reduced short-term profits (Matsa and Miller 2013). Further, greater female representation in national legislatures is related to increases in foreign aid to other countries and reallocation of such aid to health- and education-related projects (Hicks et al. 2016). Finally, increased women's representation in leadership positions is associated with future increases in women in leadership positions, presumably related to reduced gender stereotyping (O'Brien and Rickne 2016).

Conclusion

This brief entry has offered a very broad overview of the human preference for organizational hierarchies and the implications related to the attainment and use of power, in particular by males. It suggests there is a long, documented history of "men in positions of power" in social species that can be assessed in terms of the demand for male leaders and the supply of them. It further suggests this may be related to biological *and* social factors. Finally, it shows that it matters which biological sex has power.

Men Riskier, More Aggressive

Rachel A. Knoblach

Florida State University, Tallahassee, USA

Synonyms

Aggressive behaviors; Risk propensity; Risk-taking

Definition

Evolutionary, psychological, environmental, and genetic processes suggest that men are both riskier (as defined by the willingness to take risks) and more aggressive (as defined by hostile, violent behavior or attitudes directed toward another, as well as the readiness to attack or confront).

Introduction

From an evolutionary perspective, aggression and risk taking are ubiquitous across human societies and are crucial for the evolution of behavior, especially for human males (Bowles 2009). Human nature is in many ways the product of natural selection, and as a result, the traits and behaviors that helped men survive and prosper in hunting-gathering societies still exert powerful influences in the modern world; for the reproductive- and territorial-based motivations that drive men to take stock market risks or fight for the attention of females rest upon the reproductive- and territorial-based motivations to be successful.

Male aggression and risk-taking behaviors have been greatly studied because of their relevance to human behavior, the rationality of thinking, and the relative importance of genetics and environments in determining the expression of such traits among men. Notably, much of this research has documented sex differences in risk taking and aggression (Archer 2004), as well as illustrated a connection between risky and aggressive behaviors throughout evolutionary history – as seen in kinship, securing power, and mating dominance – and the modernized versions of these risky, aggressive behaviors, including financial risks and ethical risks. Overall, these lines of research have led scholars to propose that men are more willing to take risks and act aggressively (Campbell 2006; Bowles 2009). Furthermore, that sex differences are likely a consequence of various evolutionary and social explanations, including male competition over mating opportunities, life-course developmental differences between men and women, and socialized gender roles.

Male Competition over Mating Opportunities

Theories continuously seek to explain why men are riskier and more aggressive than women. Historically, Darwin's theory of sexual selection – a theory of mate choice and competition for mates – provided researchers with a way of understanding these complex sex differences. For Darwin, traits developed for the general purposes of life are due to natural selection, and traits that provide an advantage over a rival in securing a mate are instead subject to sexual selection (Darwin 1871). Therefore, his theory was simple: certain individuals have an advantage over other same sex individuals in respect to reproduction. In this way, male competition is easy to envision: males fight for women, against weaker, less-abled men, using resources associated with their body size; physical conditioning; and weaponry (e.g., horns, guns) to acquire promising mates. The male sex drive is equally as involved in the process of

procuring mates, as well as their song and dance, courting habits, readiness for re-mating, and mate guarding. Biologically, men exhibit higher testosterone levels than women, and higher endogenous testosterone levels in men have been empirically linked to aggressive, dominant, criminal, and violent behavior (McDermott et al. 2007). The male warrior hypothesis, for instance, is another evolutionary theory that refers to the idea that men engage in more aggressive behaviors because of evolved psychological mechanisms that have developed from an ancestral history of violent intergroup conflict among males, in which success increases their reproductive fitness (Daly and Wilson 1988).

Furthermore, among adolescent males, physical aggression is used to achieve social dominance and effectively compete for status, allies, and popularity (Hoff et al. 2009; Pellegrini 2008). As such, males have evolved a range of physical characteristics, biological factors, and psychological mechanisms that they use to improve their chances of gaining access to women and resources, including aggression and risk taking (Buss and Duntley 2006; Geary et al. 2003). Along the same lines, scholars continue to find that male engagement in risky activities, as well as their inclination toward aggression, reflects adaptations to increase ancestral reproductive success. In one study, women were asked to rate the attractiveness of men who were brave (i.e., took risks) or non-brave (i.e., avoided taking risks). In line with evolutionary perspectives, brave males were rated as more attractive long-term mates than non-brave males, suggesting that females prefer males who are heroic and risky (Kelly and Dunbar 2001; Farthing 2005).

Life-Course Developmental Differences Between Men and Women

Sex differences in risk-taking behaviors are even apparent in young children. In one naturalistic observation study, Ginsburg and Miller (1982) observed the behaviors of young children at a

petting zoo, and they found that young boys were significantly more likely to engage in “high-risk” activities, such as riding elephants, feeding animals, and petting the burro, compared to the young girls in the group. Similarly, other studies have shown that young boys, when shown photographs of games that vary from high risk to no risk, generally rate risk potential as lower than young girls do (Hillier and Morrongiello 1998). Additionally, sex differences in the use of direct aggression often appear in the first 2 years of life and persist through childhood and adolescence (Card et al. 2008). Together, these findings indicate that sex differences in risk taking are present early in development, suggesting the existence of a biological sex difference in the predisposition for risk-seeking behavior, with men being more inclined to accept risk than women.

Moreover, sex differences continue to appear throughout the life course. Young males are especially more likely to engage in risky behaviors, such as unsafe sex (DiClemente et al. 1990), substance abuse (Arnett 1992), and reckless driving (Tonkin 1987). This higher propensity for risk-taking behaviors has been referred to as “young male syndrome,” as it so eloquently captures the sex differences present at younger ages that continue to evolve as men develop and mature (Wilson and Daly 1985). Later in adulthood, men take greater financial risks and weigh monetary financial risk attitudes, including the possibility of loss over gain, less heavily than most women (Eckel and Grossman 2002). Men are also more aggressive than women in laboratory settings, as well as in real-life settings, whether measured by self-report (Archer 2004) or by frequencies of arrest for violent crime (Roe et al. 2009). The sex differences in aggression are even consistent across cultures (Archer 2009; Campbell 1999). Scholars have argued that men engage in risky pursuits and aggressive interactions without adequate consideration of the consequences. For example, men are more likely to take part in extreme sports (Murray 2003) and are also more likely to be overrepresented in illegal drug usage (Degenhardt et al. 2008), dangerous driving convictions (Corbett 2007), and deaths from accidents (Pampel 2001). Notably, women

have been documented as less risky, especially when the risks are physical or life-threatening, whereas men are more likely to take risks in everyday situations, such as engaging in conflict and risky sexual activity or even crossing a busy street (Byrnes et al. 1999; Campbell 1999; Poppen 1995). Scholars have further suggested that these sex differences may derive from well-established sex difference in fear of harm or injury (Campbell 2006). In childhood, girls are more fearful than boys (Else-Quest et al. 2006); and among adults, studies have also shown that women experience more intense fear than men (McManis et al. 2001; Brebner 2003).

Socialized Gender Roles

Beyond Darwin’s sexual selection theory, recent hypotheses have surfaced that seek to untangle the evolutionary reasons for sex differences in risk-taking behaviors and aggression. Zuckerman’s (1991) theory of risk as value posits that a consequence of lower levels of arousal and socially instilled beliefs that risk taking is a highly valued masculine trait motivates men to act riskier. Similarly, the masculine psychology perspective adheres to the idea that masculinity has evolved in response to the competitive demands of primitive societies, mainly that competition – in both hunter-gather societies and modern, industrial societies – forces men to engage in risk taking to gain positions of power in nature, at work, and with women (Wilson and Daly 1985).

A more recent line of research posits that differences in risk taking and aggression may be the result of socialization into gender roles that differentially encourage the use of violence among males (Eagly 1997). The observed green light for aggression and risk taking among men is likely due to a societal emphasis on evolution-based, stereotypical dominant and competitive roles understood as “manly.” Therefore, evolved differences between males and females can account for the emergence of the modern division of societal expectations and, consequently, the social roles that have surfaced to account for these differences. Researchers assert that the greater the

degree of gender inequality in a society, the greater sex differences in violence and aggression will be present (Eagly 1997). As long as the “female” gender role promotes communal behavior and the “male” gender role promotes risk-taking and aggressive behaviors, people will continue to expect women and men to possess – and act upon – these characteristics to carry out their sex-typical roles.

Conclusion

Taken together, research indicates that men can be riskier and more aggressive than women in a variety of social and biological domains. These sex differences are present early in development and continue to have a pervasive effect on behavioral patterns in males throughout the life course. More specifically, males are more willing to take risks and behave aggressively, and this propensity for risk and aggression is likely a consequence of various evolutionary and social explanations, including male competition over mating opportunities, life-course developmental differences between men and women, and socialized gender roles.

Men with Poor Mating Prospects

Kristen Syme

Washington State University, Vancouver, WA, USA

Synonyms

[Mating psychology manipulation](#); [Sexual access manipulation](#)

Definition

One model of suicide terrorism proposes that men with poor mating prospects will be more likely to commit suicide attacks as a consequence of either sexual access manipulation or as a means to increase the fitness of genetic kin.

Introduction

Statistics show that the vast majority of suicide terrorists are unmarried, young males. Among Palestinian attackers, the data indicate that 99% are male and 84.2% are unmarried (Atran 2003; Pedahzur et al. 2003), and this sex imbalance is mirrored in other communities with endemic suicide terrorism (Gunaratna 2000). Some evolutionary theorists have latched on to these demographic characteristics, asserting that males with poor mating prospects, as evidenced by their bachelor status, are more likely to commit suicide attacks. (e.g., Kanazawa 2007). While the theoretical argument that those with low reproductive potential would be more likely to self-sacrifice is sound, the evidence that males with poor mating

opportunities are more likely to engage in suicide terrorism is mixed.

Intrasexual Competition

Consistent demographic features of suicide attackers include that they are predominately unmarried males who tend to be in their early twenties (Benmelech et al. 2012). As a consequence, some evolutionary theorists have turned to intrasexual competition to attempt to explain this puzzling act. Kanazawa (2007) argued that polygyny limits younger, low-status Muslim males' access to mates. In conjunction with divine promises of sexual rewards in the afterlife, Kanazawa and later Thayer and Hudson (2010) contended that intrasexual competition and sexual access manipulations are sufficient to explain suicide terrorism from an evolutionary perspective. However, there is no evidence that suicide attackers are less likely to marry than noncombatants nor do they appear to be lower in status (Atran 2003; Berrebi 2003; Krueger and Malečková 2003). Moreover, this hypothesis is theoretically problematic. Lawson et al. (2008) noted that in gerontocratic societies where older males monopolize females, younger males should instead spend their early reproductive years acquiring resources, not engaging in behavior that results in certain death.

Alternative Theories for Demographic Characteristics

Alternative evolutionary explanations for the young age of male suicide attackers, however, exist. First, though polygyny is not likely a direct factor in the social precipitation of suicide terrorism, sexual access manipulation might play a partial role, potentially factoring into cost-benefit analyses (see ► [Sexual Access Manipulation](#)). The belief that 72 virgins await those who sacrifice their lives for religious causes in the afterlife is perpetuated by some Islamic terror organizations, and the hope that one will receive such rewards is cited as a common motivator for

suicide attack (Hafez 2006). Secondly, the veneration of suicide terrorists as martyrs by local communities might act on mating psychology (see ► [Sexual Access Manipulation](#)). Third, the hypothesis that kinship psychology manipulation motivates suicide terrorism entails that suicide terrorists will recruit individuals who are younger in age (Qirko 2004) (see ► [Kinship Psychology Manipulations](#); ► [Young](#)).

Inclusive Fitness

Another possibility is that men with poor mating prospects could improve their fitness by killing themselves and directing resources towards their kin. The inclusive fitness model of suicide proposes that one would enhance his or her inclusive fitness by dying by suicide when he or she has low reproductive potential and is imposing net costs of genetic kin (deCatanzaro 1981, 1984, 1991; de Catanzaro 1995). However, there is no evidence that suicide attackers were a burden on their kin. In fact, many suicide terrorists achieved high educational levels and are employed (Atran 2003; Berrebi 2003; Krueger and Malečková 2003). On the other hand, a preliminary model tested by Blackwell (2006) demonstrated that suicide terrorism can benefit close kin. Using the Palestinian conflict as a test case, Blackwell found that suicide terrorists with middle class backgrounds and large families could benefit their families most through suicide terrorism specifically in light of the resources that could be redirected to male siblings.

Conclusion

Statistics consistently show that suicide attackers are unmarried males in their early reproductive years. Some theorists have argued that these males have poor mating prospects, and hence, will either seek to increase their reproductive success through engaging in violent behavior or alternatively they will attempt to improve their inclusive fitness by redirecting resources to their close genetic kin. More research is necessary to test these various hypotheses.

Men's Egoistic Dominant Acts

Zachary H. Garfield
Department of Anthropology, Washington State University, Vancouver, WA, USA

Synonyms

[Male strategies](#); [Social hierarchy](#); [Social status](#)

Definition

Males display a sex-specific pattern of expressions of dominance, which is a universal feature of human psychology.

Introduction

Dominance is the use of aggression, threats, fear, and intimidation to maintain or achieve positions of social influence (Henrich and Gil-White 2001),

and evidence suggests there are important sex differences in the expression of dominance (Buss 1981). Among social animals, dominance is a common mechanism by which multiple individuals produce a linear hierarchy of social rank. When dominance-based strategies are successful, stronger, larger individuals are more likely to attain a disproportionate level of power and influence within the social group (Lukaszewski et al. 2016). Among humans, cultural and ecological context plays an important role in the viability of dominance-based strategies, and among mobile egalitarian foragers, untethered subsistence coupled with an ethos of equality allows the group to effectively resist overly assertive dominant leaders (Boehm 1993). With increased sedentarization and monopolization of resources by kin groups, the importance of dominance in status striving increases (Kaplan et al. 2009). Nonetheless, dominance represents a distinct strategy for gaining social influence across a variety of social and cultural contexts (Chapais 2015; Cheng et al. 2013) and is likely a universal feature of human psychology. Yet sex-specific expressions of dominance reveal the impact of sexual selection on male and female leader-follower psychologies.

The Expression of Dominance Among Men

Among a sample of Western undergraduates, Buss (1981) demonstrated sex differences in dominance behaviors and evaluations of dominant acts. Males showed preference for self-enhancing and egoistic expressions of dominance and rated these behaviors more favorable; similarly, dominant males reported expressing dominance through both communal and egoistic acts, whereas dominant females tended to express dominance exclusively through communal, pro-social behaviors. Both males and females may pursue dominance-based strategies for achieving positions of social influence, yet males are more likely to use dominance to achieve individual goals. For males, expressions of dominance can function to achieve both proximate goals promoting

individual accomplishments, while simultaneously working to achieve ultimate reproductive goals and increased reproductive success.

Dominance and Reproductive Benefits

In addition to the physical underpinnings of social dominance, individuals who achieve and demonstrate competence in a variety of behaviors, including fighting ability, control of fear, the ability to produce coalitions, and the cognitive abilities associated with effective strategizing, are able to more effectively display and express dominance among the group leading to leadership positions and high social status (Chapais 2015). Across a wide variety of cultural contexts, high-status males have increased mating opportunities, have access to higher-quality mates, are more likely to marry polygynously, and ultimately have greater reproductive success (Hill 1984; Neel 1980). The emphasis on status striving and the associated reproductive rewards is a component of human social organization that has remained stable over biological and cultural evolution. In a meta-analysis of 33 nonindustrial societies, von Rueden and Jaeggi (2016) documented a consistent relationship between male social status and reproductive success, independent of domains of status competition and consistent across variation in social stratification. Dominance may be expressed in many forms, including aggressive and nonaggressive mechanisms. For males, dominance is a widespread route to increased social status and ultimately increased reproductive success.

Conclusion

Over the course of human evolution, there have been strong selection pressures shaping and reinforcing status competition among males, building on the primate and mammalian systems of dominance hierarchies (Chapais 2015; Neel 1980; von Rueden and Jaeggi 2016). Males rely on physical markers to signal the propensity and potential for expressions of dominance to

the group but can also use demonstrations of competence in a variety of domains to achieve positions of social influence which may or may not confer authority and coercive power over subordinates (Chapais 2015). At both the proximate and ultimate levels, expressions of dominance among males serve individualistic and egoistic aims, conferring social status and reproductive benefits. From this system, cooperative and pro-social behaviors may emerge as well. Human males have evolved to be status seekers, and the pursuit of dominance-based strategies for achieving positions of social influence remains a universal feature of male psychology employed by at least some males across a wide range of social and cultural settings.

Men's Mate Preferences

Daniel Kruger

University of Michigan, Ann Arbor, MI, USA

Synonyms

[Ideal partner preferences](#); [Mate choice criteria](#); [Mate selection criteria](#); [Partner preferences](#)

Definition

The characteristics which men use to evaluate potential relationship partners, especially those in contrast to the characteristics women use to evaluate potential relationship partners. Men place more value on cues of youth and fecundity, whereas women place more value on social status and potential for resource provisioning.

Introduction

Systematic research has documented sex differences in preferences for romantic and marital partners since the early twentieth century. These studies revealed many findings consistent with current theory and research in evolutionary psychology. For example, college-aged women prefer partners older than themselves, whereas college-aged men prefer partners younger than themselves, matching patterns in contemporary census records (Hill 1945). Men and women

showed considerable agreement in preferences for mate attributes, such as agreement on dependable character, emotional stability, and maturity, pleasing disposition, mutual attraction, and good health. However, several sex differences were evident. Women gave more consideration to ambition and industriousness, education and general intelligence, and good financial prospects than men did, whereas men gave more consideration to being a good cook and housekeeper, good looks, and desire for home life and children (Hill 1945). Men in fraternities were more demanding, ascribing more importance to nearly all characteristics than nonaffiliated men. Hill (1945) suggested that fraternity men could insist on higher standards because of their higher social status on campus. Other than this reasonable inference, the researchers made no attempts to explain the patterns of findings. The results were purely descriptive; there were no *a priori* hypotheses reported or tested.

Over the years that followed, the questionnaire from the University of Wisconsin study of campus values in mate selection (Hill 1945) became the foundation for sociologists' studying patterns in marriages and families. Buss (1989) utilized this survey in a study of ideal partner preferences across 37 cultures and framed mate selection in the context of evolutionary selection pressures. The study confirmed theoretical predictions across the human population; although women and men share values and preferences for many characteristics, differences between the sexes are also evident. Women place more value on cues to resource acquisition in potential mates, whereas men place more value on cues to reproductive capacity (Buss 1989). The publication of this study was a defining event in the emerging field of evolutionary psychology, leading to a considerable volume of research on sex differences in mate selection criteria.

Evolutionary Foundations for Sex Differences in Human Mate Preferences

Evolution by sexual selection occurs through two processes, intrasexual competition and intersexual

selection (Darwin 1871). Intrasexual competition consists of contests between members of one sex, where the winner of the contest gains preferential access to members of the opposite sex. The prototypical example of intrasexual competition is buck deer locking horns in combat during the mating season. The winner of the bout gains the territory and access to the females within it; the loser goes home with a broken horn. This process continues year after year, and any heritable variation that promotes success in these contests will spread through the population over many generations (Darwin 1871). Human intrasexual contests may be subtler.

Intersexual selection involves both sexes. If members of one sex have a consensus about the desirable characteristics of the opposite sex, then those individuals with the desired characteristics will have a mating advantage. One example is the size and decorative coloration of feathers seen on many male birds. It is hypothesized that the underlying reason why female birds find a male peacock's tail feathers attractive is their indication of the survival ability of male birds. The feathers would not only be noticeable to females but also to predators and a hindrance in movement, making escape from predators as well as routine tasks more difficult. It would seem easier to survive without this costly display; the females of the species usually possess coloration that blends in well with the features of the habitat. The birds that are able to survive with this handicapping display must also have some characteristics that would be valuable for the female's potential offspring to acquire (Darwin 1871).

Among mammals and most other animals, females are the limiting sex in reproduction because they provide almost all of the physiological resources required for offspring production. The larger investments allocated to offspring result in much lower potential reproductive capacities in females compared to males. Because of these factors, females are more discriminating in mate selection, and males exert comparatively more effort than females in attracting and retaining mates (Trivers 1972). For males in most species, reproduction is limited by access to fertile mates, more so than for their female

conspecifics (Trivers 1972). Thus, cues of fertility and reproductive value will be more prominent in men's mate preferences than in women's mate preferences.

Reproductive value is the expected future contribution to offspring in future generations. Fertility is the likelihood of being able to reproduce at a given time. Although life history patterns will vary somewhat across cultures, women's fertility typically peaks in the early 20s, with a gradual decline until menopause (Bongaarts and Potter 1983). Reproductive value peaks earlier, typically in the mid-teens, and then declines linearly with age. Although cultural norms, reproductive practices, and age-specific mortality will vary across cultures, women's reproductive value and fertility are strongly age-dependent (Williams 1957). Thus, cues of age will be important in men's mate preferences.

Aspects of Men's Mate Preferences

Women and men share preferences for partner characteristics such as kindness, understanding, and intelligence (Buss 1989); however, preferences also show divergence following reproductively relevant currencies. Physical features and behavioral indicators associated with youthfulness are hypothesized to predict women's reproductive capacity and thus men's mate preferences. In addition to studies of attribute ratings, other studies have found that levels of physical attractiveness in photographic stimuli influenced men's evaluations more so than women's evaluations (e.g., Townsend and Levy 1990). These sex differences are evident in preferences for both long-term and short-term partners, although the differences may be smaller in short-term preferences (Li and Kenrick 2006). Several specific aspects are reviewed below.

Facial Features

Cunningham (1986) found that "baby face" features, i.e., large eyes and a small nose, were consistently correlated with attractiveness in women, perceived fertility, and perceptions of few medical

problems. Studies using both actual (Cunningham 1986; Grammer and Thornhill 1994) and computer-manipulated (Perrett et al. 1998) images find that women's faces with more feminine features are perceived as more attractive. The degree of feminine features in women's faces is related to levels of circulating estrogen (Law-Smith et al. 2006), suggesting a connection to health status.

Research has identified other facial attributes that enhance women's attractiveness. Symmetrical faces are more attractive, as they indicate stable morphological development with good nutrition and without significant injuries or contagion from pathogens, as well as a good match between genotype and the developmental environment (Møller 1997). Studies using both unmanipulated images of real faces (Grammer and Thornhill 1994) and sophisticated computer graphic simulations (Rhodes et al. 1998) demonstrate that facial symmetry predicts attractiveness. Individuals with more symmetric faces are perceived to be healthier (Jones et al. 2001). Some studies suggest that these perceptions are accurate, as facial symmetry is inversely related to incidents of respiratory disease (Thornhill and Gangestad 2006) and directly related to features suggesting good physical condition (Little et al. 2008).

Facial averageness, the degree to which one's face resembles most other faces in a population, also predicts facial attractiveness. Average faces may be attractive because they indicate genetic diversity, which confers resistance to pathogens and/or because those with average faces are less likely to be homozygous for deleterious alleles (harmful mutations) than those with less average faces (Mitton and Grant 1984). Facial averageness is in fact predictive of better health status (Rhodes et al. 2001) and genetic diversity in the histocompatibility complex (MHC) genes that code for immune response proteins (Lie et al. 2008). MHC gene heterozygosity in itself is predictive of perceived facial attractiveness (Roberts et al. 2005).

Body Features

Research has demonstrated similar patterns in preferences for women's other bodily features.

For example, breast symmetry is attractive and is positively correlated with fecundity (Little et al. 2011). Skin tone is an honest indicator of youthfulness and fertility (Fink et al. 2001). The number of physical attributes predicting both attractiveness and beneficial attributes will continue to grow with future research.

Waist-to-Hip Ratio

Another salient characteristic in humans is the ratio of the circumference of the waist to the hips. Before puberty, men and women have a similar distribution of fatty tissues, but afterwards women have a smaller waist-to-hip ratio. A smaller waist-to-hip ratio in women is associated with better health status and greater reproductive capacity (Singh 1993). Across decades of cultural and fashion changes in the USA, a small waist set against full hips was a consistent feature of female attractiveness, whereas bust line, overall body weight, and physique varied over the years (Singh 1993). Although the original stimuli were rather crude, male preferences for low waist-to-hip ratios (around 0.7) are replicated with precise digital stimuli disentangling waist-to-hip ratio and body mass covariation (Kościński 2014).

A large pelvis facilitates delivery in childbirth, which is more difficult in humans due to infants' large heads and a pelvis adapted for bipedal locomotion. A narrow waist also signals the absence of pregnancy and therefore current fecundity, one of the few easily perceptible cues of a woman's status (Singh 1993). Women in the optimal 0.7 WHR range have better health status, fewer medical conditions, and lower mortality (Singh and Singh 2011). These women have higher fecundity (Zaadstra et al. 1993) and higher rates of pregnancy (Singh and Singh 2011).

Faithfulness and Paternal Uncertainty

Both women and men are upset by sexual and emotional infidelity in partners; however, sexual infidelity is more upsetting to men than to women because of the threat of diversion of paternal investment to children fathered by other men

(Buss et al. 1992). Men will have mate selection preferences that protect against paternal uncertainty; however, the form of these preferences will vary across history, culture, and population. In natural fertility populations, men may value chaste women as this would provide a cue to paternity confidence both at the current time and in the future (Dickemann 1981). Women's chastity is valued across cultures; however, there is variation in its importance (Buss and Schmitt 1993). Across cultures, men are likely sensitive to women's overt expressions of mating effort. Although men would consider flirtatious women for short-term sexual relationships, they are less likely to desire them as long-term relationship partners (Kruger et al. 2014).

Conclusion

Men's mate preferences include a variety of personality, behavioral, and physiological features all related to the potential to promote men's reproductive success. There will be trade-offs between specific features, and assortative mating will lead to partnering between men and women of similar value in the mating market. Women's intrasexual competition will emphasize features attractive to men in efforts to attract and retain mates.

[Men's mate preferences](#); [Men's short-term mating](#)

Definition

Mating strategies often differ between men and women, as well as between short-term and long-term contexts. Men seeking short-term mating opportunities are expected to employ strategies that will minimize investment in potential partners and offspring while maximizing opportunities for casual sex.

Introduction

Men and women differ in their minimum investments to their offspring, with women typically investing much more in their children than men. As a result, men and women tend to differ in the genetic benefits they stand to gain from a short-term mating strategy – one in which a person pursues short-term mating opportunities, usually with little investment in their partner. Over a 9-month period, a woman could only give birth to a single child, whereas a man could potentially sire numerous children over the same length of time. Therefore, the potential genetic benefit of a short-term mating strategy is much greater for men than for women. Men and women in all

cultures do tend to gravitate toward monogamy, with both men and women often adopting a mixture of short-term and long-term mating strategies that vary depending on environmental contexts. Nevertheless, data from men and women across many cultures suggests that men may be more likely to pursue a short-term strategy than women.

Strategies

Sexual strategies theory (SST; Buss and Schmitt 2017) asserts that because men and women faced different challenges to reproductive success, they evolved different strategies to overcome these challenges. Men, for example, likely faced the challenge of acquiring multiple, willing sexual partners whereas women faced the challenge of securing investments from their intimate partners. There are also individual differences in mating psychologies within sexes, characterized by Buss and Schmitt (1993) as either short-term or long-term. Short-term relationships often involve sex without considerable investment, such as one-night stands, or friends with benefits. Long-term relationships generally involve prolonged commitment to the same individual, like in marriage. Men and women typically employ a combination of short-term and long-term strategies, and these strategies differ between men and women.

Adaptive Problems Faced by Men Pursuing Short-Term Strategies

Partner Number

Men pursuing short-term mates face a different set of obstacles than those pursuing long-term mates. In general, men who maximized their number of sexual partners would have been more reproductively successful than men who had relatively few sexual partners. In response to these selection pressures, men have developed several adaptive psychologies. Specifically, men typically desire a large number of sexual partners, relax their standards for short-term (compared to long-term) partners, and prefer to

have sex quicker, rather than wait to have sex after first meeting someone (Schmitt et al. 2001).

Minimizing Risk and Investment

Identifying Sexually Accessible Women

When attempting to mate with many different partners, men face the problem of identifying which women are sexually accessible. Men seeking short-term mates would be unlikely to pursue relationships with women who appear sexually reserved or seem unlikely to consent to sex without considerable investment. Although men seeking a long-term partner may find promiscuity undesirable, promiscuity is a good cue to men seeking a short-term partner that they will not have to invest heavily to gain sexual access. Men who could maintain sexual relationships while preventing investments in their partners from escalating were likely able to pursue more short-term relationships (Buss 1994). Men may even pursue short-term relationships with women interested in long-term mating by exaggerating or lying about their willingness to commit for extended periods of time (Tooke and Camire 1991; Jonason & Buss 2012). Where women's preference for sexual permissiveness remains constant regardless of mating context, men considering a short-term mate report a greater preference for sexual permissiveness than do men considering a long-term mate (Oliver and Sedikides 1992).

Identifying Fertile Women

Men seeking a short-term partner face the problem of identifying fertile women. Men seeking long-term partners also face the problem of identifying fertile partners but are predicted to be more concerned with cues to future fertility (maximizing potential future children of the length of the relationship), whereas men seeking short-term partners would likely be more attuned to cues of current fertility. As youth is a reliable predictor of future fertility, men would predictably be more interested in young women when pursuing a long-term strategy. But because age cannot be directly observed, men seeking fertile mates would likely attend to cues that reliably covary with age, such as attraction. Unsurprisingly,

Buss and Schmitt (1993) found that men seeking short-term mates placed more emphasis on attractiveness than did men seeking long-term mates.

Behaviors

Infidelity

Behavioral evidence from large samples of men in various cultures indicates that they pursue short-term strategies more often than women. Both men and women sometimes pursue a mixed strategy, in which they maintain commitment to a long-term partner while seeking mating opportunities with one or more short-term partners. Although both men and women in monogamous relationships sometimes seek extrapair partners, they differ markedly in the type and frequency of extrapair copulations they pursue. A series of surveys from 1991 to 2010 revealed that among American participants who had ever been married, 20–25% of men had cheated on their spouse, compared to 10–15% of women (Carr 2010). Although women could certainly benefit from pursuing extrapair copulations, they historically risked violence and sexual assault at the hands of their monogamous partners if they were suspected of infidelity. Men also face risks to infidelity, such as violence from male relatives and partners of the women they copulated with, and retaliatory infidelity from their own spouses. Nevertheless, men seem to be more interested in extrapair copulations than do women.

Hook-Ups

Men seem to be more interested in casual, one-time sex partners than women. Hook-ups and friends with benefits situations are typically those in which the relationship is sexual, but there are no explicit promises of continued commitment. Men, more than women, report sexual fantasies involving multiple, anonymous women, and men are more likely than women to report having at least one friend with benefits (Garcia and Reiber 2008). Women, on the other hand, report more depression and regret following one-night stands and when asked what they want out of hook-ups, women more often respond with hopes that the hook-up will lead to a long-term

romantic relationship (where men often hope that they get to have more hook-ups). Women do, of course engage in short-term mating, but the motivations for doing so appear to be different from those of men.

Prostitution

The exchange of goods or currency for sex occurs in most known cultures and is frequently referred to as “the world’s oldest profession.” Most solicitors of prostitution are male, and a large proportion of men have solicited prostitution – 69%, according to Kinsey et al. (1948, 1953). The widespread prevalence of male solicitation of prostitution is yet more behavioral evidence for the male preference for short-term mating opportunities.

Sociosexual Orientation Inventory: Behaviors

The sociosexual orientation inventory (SOI; Simpson and Gangestad 1991) and its revised version (SOI-R; Penke & Asendorpf 2008) were developed to measure willingness and desire to engage in multiple, uncommitted sexual relations, as well as frequency of past sexual behaviors. Simpson and Gangestad observed that reports of sociosexual attitudes were generally correlated with reports of sociosexual behaviors. Specifically, individuals who expressed unrestricted attitudes about casual sex were more likely to have engaged in sex with more than one person during the same period of time and reported having sex earlier in their relationships. Conversely, those who expressed more restricted attitudes on the SOI were less willing to engage in sex without commitment and investment from the other partner. Importantly, Simpson and Gangestad (1991) provided evidence that more casual attitudes towards sex, and greater desire for multiple casual, sexual experiences correlated with a greater frequency of past sexual encounters.

Contextual Influence on Mating Strategies

Perceived Effectiveness of Short-Term Strategies

When men do seek short-term partners, they typically emphasize traits that they believe are

desirable to women seeking a short-term relationship (Schmitt and Buss 1996). Schmitt and Buss (1996) observed that both men and women predicted that men displaying cues indicating current ability to share resources and cues indicating dominance would be more successful in pursuing short-term relationships. Indeed, men, more so than women, have been observed to deceive potential partners in order to gain sexual access, exaggerating their future willingness to commit to relationships, inflating their status and earning potential, and acting more agreeable and dominant than they really are (Tooke and Camire 1991). The willingness of men to lie about these cues is unsurprising, given that women tend to prefer cues to high status, high earning potential, willingness to commit, and agreeableness (Buss 1989; Buss et al. 2001; Shackelford et al. 2005) tested.

Father Absence

Pursual of a short-term mating strategy appears to be correlated with father absence in both men and women. Mayan and Ache men without fathers were less willing to invest in a long-term romantic relationship compared to those with fathers (Wanforth et al. 1998). Further, men raised without fathers appear to experience puberty earlier and are more likely to pursue a short-term mating strategy (Ellis et al. 1999; Surbey 1998). It is unclear to what extent genetic heritability plays a role in fatherless men’s unwillingness to pursue a long-term strategy, and the societal impact of growing up without a father should also be considered as a potential explanation.

Life Stage

Men and women also seem to change their sexual strategies across their life spans. Short-term strategies are more common among adolescents and decrease with age. Frayser (1985) explained that adolescents engage in short-term mating as a way of assessing their own mate value and exploring their preferences. It may also be the case that adolescents possess attributes such as attractiveness that make them more successful in short-term contexts, thus making them more likely to pursue short-term mates.

Mate Value

Unsurprisingly, there does appear to be a correlation between self-perceived desirability and number of sexual partners for men. According to Clark (2006), men who perceived themselves as more sexually desirable also reported having more sexual partners. But self-perception of mate value is not the only predictor of more sexual partners; men with desirable short-term attributes such as masculine bodies and faces, and access to status and resources tend to have more sexual partners (Kanazawa 2003; Perusse 1993; Rhodes et al. 2005). These data suggest that men may generally be more likely to pursue a short-term strategy when they perceive a greater likelihood of short-term mating success.

Sex Ratio

The amount of sexually available partners has been observed to influence the adoption of different mating strategies. Specifically, in contexts with a majority of women, men are more likely to pursue short-term mating opportunities. Inversely, when there are more men than women, individuals are more likely to pursue long-term mates, and even to have fewer divorces (Pedersen 1991).

Conclusion

Although men and women generally express preferences for long-term partners and value partners who indicate good parenting skills, men's mating behaviors diverge from women's in several notable respects. Notably, men express greater desire for multiple sexual partners and are more likely to act on this desire by having extramarital affairs and other types of short-term mating arrangements.

Men's Suspicions of Partner Infidelity and Women's Defection

Caroline Braun
Department of Psychology, Oakland University,
Rochester, MI, USA

Synonyms

Cuckoldry; Forced In-pair Copulation (FIPC); Intimate Partner Violence (IPV); Paternity Uncertainty

Definition

The tendency for men to use intimate partner violence (IPV), forced in-pair copulation (FIPC), and in some extreme instances, homicide as a means of reducing the threat of cuckoldry and relationship defection.

Introduction

More than ten million Americans, both male and female, are victims of intimate partner violence (IPV) each year (Black et al. 2011). Yet women are disproportionately more likely to be victims, with 82% of IPV victims in the United States being women (Truman and Morgan 2014) and are disproportionately more likely to be physically abused by men, with 99% of female IPV incidents being perpetrated by men (Catalano et al. 2009). Although rates of IPV are quite high, being a perpetrator of IPV comes with many potential consequences. Men who physically abuse their partners may lose their partner if she defects from the relationship; lose access to their children; have to serve time in jail; have to pay large legal fees; experience reputational damage from friends or family; and lose out on employment opportunities. Despite these negative, proximal consequences, an evolutionary perspective suggests that physical and sexual abuse may solve adaptive problems recurrently faced by males throughout our species' evolutionary history. Indeed, the two most common reasons men report for having been physically abusive towards their partner is their suspicion of an infidelity and/or the perception that their partner is attempting to defect from the relationship (Wilson and Daly 1996). The purpose of this entry is to explain why men may have evolved adaptations that favor intimate partner violence in the contexts of infidelity and relationship defection, despite the costs associated with IPV.

Evolutionary Foundation

Parental Investment Theory

Parental Investment Theory (PIT) was proposed by Trivers (1972) as an explanation for humans' sexual behavior, including sexual selection and mate preferences. According to PIT, the sex that invests more in its offspring will be more discriminating when it comes to selecting a mate, whereas the sex that invests less in its offspring will be less

discriminating in selecting a mate. In most species, females invest the most in offspring. Women's greater investment in their offspring begins with their gametes; in comparison to men, who produce millions of sperm daily, women produce a fixed number of large (relative to sperm), energetically costly, non-replenishable eggs in their lifetime. Women's larger investment continues with internal fertilization and gestation, which requires a minimum 9-month investment of time and energy, in comparison to just a single ejaculation for the man. Ancestrally, women also engaged in a long period of breast-feeding, and took on a larger role in parental care than men. Because of their greater investment, women are a valuable reproductive resource. In order for a man to pass on his genes, his offspring must survive into adulthood and have offspring of their own to continue passing their father's genes on to future generations. This requires offspring be protected, nurtured, fed, and taught essential survival skills, the majority of which are typically done by the mother.

Because of this immense investment required from the mother, evolution favored women who were selective in choosing high-quality mates, as selecting the wrong mate could lead to decreased reproductive success and fewer of their offspring surviving to reproductive age. Given that women are more selective, they may consider or resort to cuckoldry if their mate is of low mate value. Cuckoldry occurs when a man invests parental efforts and/or resources in offspring that are not genetically his. Cuckoldry may serve as a dual-mating strategy in which a woman remains with a long-term mate who provides resources but simultaneously pursues short-term mating opportunities with high genetic quality partners. Such a strategy is particularly likely to be enacted when the long-term partner is of low mate value. Indeed, research indicates that women who rate their partners as being low on sexual attractiveness report a greater desire for extra-pair mates when ovulating (Pillsworth and Haselton 2006).

Women's mating preferences also shift during ovulation, with women preferring men with symmetrical features, facial masculinity, body masculinity, and vocal masculinity at peak fertility

(Gildersleeve et al. 2014), all of which are indicators of genetic quality. Given that women are most likely to conceive during ovulation, copulating with a short-term partner, especially one of high genetic quality, would allow a woman to secure better genes to pass on to her offspring. By simultaneously remaining with her long-term partner, she would also still be receiving resources from him, provided that he was not aware of the infidelity. The woman would continue to receive resources from her long-term partner through the pregnancy and rearing of the offspring, as the woman would have cuckolded her long-term partner into raising the offspring of another man.

Cuckoldry and Paternity Uncertainty

Although parental investment theory observes that women typically invest more in their offspring than men, men's investment is not negligible, and men who invest in their offspring have a lot to lose in the event that their partner cuckolds them. Men's risk of being cuckolded is heightened by concealed ovulation. In comparison to female chimpanzees, whose genitals swell bright red when their eggs are released (estrus) and thus signal to the male chimpanzees that the females are able to conceive, women give no visible indication that they are ovulating. Most sexual activity for chimpanzees takes place during this phase of genital swelling, whereas humans copulate throughout the menstrual cycle. Given that male chimpanzees are visibly aware of when females are ovulating, a male could mate guard a female as soon as she entered estrus, thus ensuring that he is the only male she mates with during ovulation. This allows the male to be fairly certain of his paternity (Buss 2015, p. 148). Among humans, although women give off subtle cues that they are ovulating, men cannot be certain of when ovulation occurs. As a result, men are not able to mate guard to the same extent that male chimpanzees are, given that it would need to occur for the entire length of the menstrual cycle in the absence of any cues to ovulation. This is not feasible since men have other adaptive problems to solve, such as how to acquire resources. Concealed ovulation coupled with men's inability to mate guard without interruption gives women the opportunity to

furtively mate with other men, thus cuckolding her current mate by tricking him into raising the offspring of another man.

Men who are cuckolded face significant reproductive costs, including: investing wasted time and resources into offspring that are not his; wasting time and effort in selecting, courting, and maintaining the relationship with his mate; losing opportunities for short-term and long-term mating with other women; directing his parenting efforts into a rival's offspring, especially if more effort is directed to his rival's offspring than his own offspring; and acquiring reputational damage (Buss and Duntley [under review](#)). The latter may especially detrimental, as reputational damage may prevent him from raising his status and finding future mates, as well as possibly decreasing his mate value as both men and women may assume that he's unable to prevent mate encroachment or physically protect women. Because the costs of cuckoldry are so significant, men may have evolved psychological adaptations to aid them in identifying and responding to an actual or perceived act of cuckoldry.

Partner Infidelity

Violence

Sexual jealousy has been identified as the leading cause of IPV (Buss and Duntley [2011](#)). Men, in comparison to women, exhibit more sexual jealousy, as a woman becoming sexually involved with another man could signal to her current partner an impending affair, and thus the possibility of cuckoldry (Kaighobadi and Shackelford [2008](#)). From an evolutionary perspective, sexual jealousy is hypothesized to function as a mate retention tactic that solves the adaptive problem of cuckoldry (Daly et al. [1982](#)). By experiencing sexual jealousy, men are able to pick up on circumstances that may make them susceptible to an impending cuckoldry, such as when their partner is flirting with another male. By picking up on such cues, men can use mate retention tactics to prevent their partner from copulating with another man, thus preventing themselves from being cuckolded.

Sexual jealousy can manifest as a variety of behaviors, ranging from seemingly harmless mate retention tactics, such as buying flowers for a mate or sitting next to her when another male is present, to more severe tactics such as IPV and partner rape (Buss [1988](#)). Mate retention behaviors are hypothesized to be performed hierarchically, with less severe or less costly mate retention behaviors being performed first, followed by more severe or more costly behaviors (Kaighobadi et al. [2008](#)). In the event that a woman has been copulating with another man, her partner may be motivated to use physical violence as means of protecting himself from being cuckolded by preventing any further extra-pair copulations. This is especially true if the man initially used nonviolent mate retention tactics, such as verbal threats, to deter the extra-pair copulation, but such tactics were unsuccessful.

According to Wilson and Daly ([1996](#)), men use violence against women as a risky strategy for deterring their partner from an infidelity. When used strategically, violence can increase the credibility of threats. If a man discovers that his partner is copulating with another man, he may initially threaten his partner with violence. However, if the man does not follow through with his threats, they become ineffective at deterring his partner from future extra-pair copulations. In this situation, acting on his threats by inflicting violence on his partner would increase the credibility of any future threats, as this would indicate that he intends to follow through on them. By increasing the credibility of his threats with an act of violence, the man would be able to use threats without having to resort to violence in the future.

Evidence that violence may serve the function of preventing cuckoldry comes from contexts that imply a woman has been involved with another man. One of these contexts is when she is or is expected to be pregnant by another man. Although the hypothesized function of violence as a response to an infidelity is to deter the infidelity and thus eliminate the threat of cuckoldry, the hypothesized function of violence as a response to a pregnancy is to terminate the pregnancy (Buss and Duntley [2011](#)). Although the function of violence differs, infidelity and

pregnancy with another man's offspring represent two very similar adaptive problems, as one signals the possibility of cuckoldry and the other signals that cuckoldry has already occurred. Empirical evidence supports this; Taillieu and Brownridge (2010) found that women who were abused while pregnant were more likely to be pregnant with another man's offspring.

Women's risk of being a victim of IPV is also heightened by the presence of stepchildren in the home (Goetz et al. 2008), as the presence of children fathered by another male implies that her current partner is investing resources in another man's offspring. Interestingly though, a woman's actual interest in another man is not the strongest predictor of IPV – but rather a woman's *perceived* interest in another man (Cousins and Gangestad 2007). If a man perceives that his partner is interested in other men, regardless of whether she actually is, she is more likely to be physically abused. Furthermore, men who make accusations of partner infidelity are more likely to use violence (Kaighobadi and Shackelford 2009). By engaging in violent behavior when accusing their partner of an infidelity, regardless of whether their partner is truly interested in another man, men are using sexual jealousy as a strategy to detect the possibility of cuckoldry. Men then respond to the threat of cuckoldry with violence, which functions to deter their partner from actually cuckolding them.

While an initial act of violence may decrease the likelihood of having to use violence as a mate retention strategy in the future, some men may be especially likely to express sexual jealousy through violence. For instance, men who lack resources may be more likely to use violence to deter an infidelity than men with greater resource access (Wilson and Daly 1993). These men may have to resort to other, more extreme methods of deterrence, whereas high-status men can use their resources as a positive incentive to keep their partner in the relationship. This is not to say that high-status men are not susceptible to cuckoldry, as women may still seek other mates if their partner is high in status but low in genetic quality, just that high-status men may be able to use their resources to manipulate their partner into staying in the relationship. Indeed, research shows that

men with lower mate value have been found to be more likely to engage in spousal violence as a means of hindering an infidelity (Buss and Duntley 2011; Wilson and Daly 1993). Furthermore, in a study examining risks for female homicide in abusive relationships, male unemployment, which would indicate a lack of resources, was revealed as the only demographic risk factor that significantly predicted female homicide risk (Campbell et al. 2003). By failing to provide his partner with necessary resources, a man may thus be inadvertently increasing his chances of being cuckolded by causing his partner to seek out resources from another mate. Without resources, there is little incentive for her to stay in the relationship, and so violence may be the only way to protect himself from a potential cuckoldry and to maintain secure reproductive access to his partner.

Partner Rape

Partner rape, also referred to as forced in-pair copulation (FIPC) may function as another, more extreme anti-cuckoldry tactic. Several studies offer support for this theory of FIPC. Finkelhor and Yllo (1987) found that partner rape was more likely to occur after accusations of female infidelity. Camilleri and Quinsey (2009) reported that convicted partner rapists, in comparison to men convicted for nonsexual partner violence such as physical assault, experienced more situations in which they were susceptible to cuckoldry prior to the crime. Finally, Shields and Hanneke (1983) observed that 47% of married women who reported engaging in an extra-pair copulation were raped and beaten by their husbands.

If an actual or perceived infidelity has occurred, FIPC could be used by the woman's partner as way of ensuring his paternity through sperm competition. Sperm competition occurs when the sperm of two or more males are present in the female's reproductive tract at the same time and compete to fertilize her egg. Evidence for sperm competition comes from changes in men's sexual behavior that occur when there are suspicions of female infidelity. For instance, men's sperm count increases when another man's sperm may be present in his partner's reproductive

tract (Baker and Bellis 1995), thus increasing his probability of securing paternity over his partner's egg. Men's sperm count also increases in proportion to how long they have been apart from their wife: the more time the couple spends apart, the more sperm the man produces (Baker and Bellis 1995), as time spent apart could provide his wife with an opportunity to copulate with another man. In addition to their sperm count increasing with the duration of separation, men's reported sexual interest in their partner increases relative to the amount of time the couple has spent apart (Shackelford et al. 2007). An increase in sexual interest would make it more likely that the couple would copulate upon reuniting, which would subsequently increase the man's chance of fertilizing an egg should another man's sperm also be present in his partner's reproductive tract. It is thus the couple's time spent apart, rather than the time since the couple's last copulation, that is predictive of sperm competition, as the unaccounted time presents a risk for cuckoldry.

FIPC may also be triggered by cues from women. For instance, Thornhill and Thornhill (1992) suggest that women who purposefully resist or avoid copulating with their partner may be doing so because of a recent infidelity. This may be especially true if their partner is low in mate value, and they are employing a dual-mating strategy in which they attempt to secure better genes for their offspring from another man who is high in mate value whilst still remaining with their current partner to continue benefiting from his resources. In order to ensure that her offspring receives the genes of her short-term mate, she would need to avoid copulating with her partner until her short-term mate's sperm fertilized her ovum, as sperm competition would jeopardize her chance of securing better genes. In this situation, the woman's resistance to copulate would signal to her partner that he may be at risk of being cuckolded, and FIPC would function to decrease this risk. Finkehlor and Yllo's (1987) finding that most instances of FIPC occur during or after defection from the relationship lends support to his hypothesis, as men are likely hyperaware of female infidelity during separation as this gives women the opportunity to seek out other mates

Defection from the Relationship

Violence

In a similar manner to a partner's infidelity, a woman defecting from the relationship can also be costly for the man (Buss and Duntley [under review](#)). Defection from a relationship represents a direct loss of reproductive access to his mate. Whereas a man may continue to have reproductive access to an unfaithful mate, any reproductive access to that mate is eliminated once the relationship has been terminated. Furthermore, ending the relationship also means that his partner is now sexually available to other men, including any potential rivals the man may have. A man's reputation could also be damaged if knowledge of the relationship ending becomes public. This could hinder future reproductive opportunities with other mates, as public knowledge of the defection may lead to a decrease in mate value. This would be especially true if the woman defected from the relationship because her partner failed to provide her with necessary resources. If other women became aware of this, this could jeopardize any future reproductive opportunities for the man, as his failure to provide his former partner with resources would signal that he is an inadequate mate.

Because of the reproductive and reputational harm, violence may be used as a strategy to prevent women from ending the relationship (Kaighobadi et al. 2009). Indeed, women who leave their husbands are often pursued, threatened, and assaulted (Wilson and Daly 1996). Men may be especially likely to resort to violence if they expect that their partner is ending the relationship for another mate. Barbaro and Shackelford (2016) found that men who were physically violent towards their partner secured more in-pair copulations per week in the previous month compared to men who weren't physically violent towards their partner. In addition, average monthly rates of violence towards female partners were positively associated with in-pair copulation frequency. By engaging in IPV and subsequently securing more in-pair copulations, the man may be using violence to both deter his partner from engaging in any extra-pair copulations and to keep

his partner in the relationship with him should their increased in-pair copulations result in fertilization. If the woman is pregnant, she may be less likely to seek out other mates as having a reliable source of resources during the pregnancy would be necessary, and it would be unlikely that another man would provide her with those resources if they were aware that she was already pregnant. However, if his partner was already thought to be copulating with another man prior to defecting from the relationship, securing more in-pair copulations through violence would serve as a mate retention tactic by deterring his partner from continuing the extra-pair copulations, as well as a sperm competition tactic by ensuring that his sperm outcompetes the other man's sperm.

Homicide

Using violence as a mate retention tactic is certainly destructive; however, mate retention takes its most extreme and lethal form through another tactic: homicide. Although rare, men may kill their partner to prevent her from defecting from the relationship, and research on homicidal relationships supports the rare instances when homicide is used as a gruesome mate retention tactic. For instance, in an in-depth interview with 30 women who had survived an attempted partner homicide, Nicolaidis et al. (2003) found that 32 women reported that their partner attempted to kill them when they threatened to terminate the relationship. Another study found that women who were separated from a male partner that they had previously lived with were at a heightened risk of being killed, as were women who had ever attempted to leave the home or had asked their partner to leave the home (Campbell et al. 2003). Furthermore, the risk of being a victim of female homicide increased ninefold if their partner was highly controlling and physically abusive *and* if the couple separated after living together. While not true for all men, it seems that a partner's departure triggers a homicidal thought response in men, as husbands who murder their wives justify the murder as a reaction to their wife leaving the relationship (Wilson and Daly 1996). In addition, studies of homicidal fantasies reveal that men often consider killing women who have rejected

them, although they do not act on such thoughts (Buss and Duntley [under review](#)).

While killing a partner may seem counterintuitive and maladaptive, as this would eliminate all reproductive access to that woman, Buss and Duntley ([under review](#)) propose that partner homicide as a response to the woman defecting from the relationship may solve two adaptive problems. First, killing the wife inflicts reproductive costs on rivals. By killing a wife who has terminated the relationship, the rival is denied all reproductive access to her. In addition, if the wife is carrying the rival's offspring at the time of the defection, killing her would also abort the rival's offspring. The second adaptive problem that is solved is preventing reputational damage that may result from the defection becoming publicly known. Although killing a mate may result in reputational damage in and of itself, killing a mate that has defected signals that the man is not someone to be messed with and may deter future mates from defecting the relationship by showing them that defection comes with grave costs. Buss and Duntley predict that the higher the mate value of the wife who ended the relationship, the greater the consequences of killing the wife for the rival as this would prevent the rival from gaining the reproductive benefits, such as good genes, from this woman. Research supports this prediction: young women (e.g., women higher in mate value) are more likely to end unsatisfactory relationships, gain the attention of sexual rivals, and form new relationships than older women (Wilson and Daly 1993). Young wives are also more likely to be killed by their husbands, with wives in their teenage years being at the greatest risk and postmenopausal wives, who can thus no longer conceive and therefore no longer pose a reproductive risk to their husbands, being at the lowest risk (Daly and Wilson 1988).

Conclusion

From an evolutionary perspective, sexual jealousy functions to solve the adaptive problem of cuckoldry. Because men who are cuckolded would be unwittingly investing their resources in another

man's offspring, overtime evolution favored men who were able to detect and prevent cuckoldry from occurring. Violence triggered by sexual jealousy serves to prevent cuckoldry in high-risk situations that indicate that the man's partner could have been involved with another man, most notably during an infidelity and relationship defection. Although IPV may be used to deter the man's partner from having an affair (Wilson and Daly 1996), men may resort to other methods, such as partner rape or homicide, if an affair has already occurred or his partner has defected from the relationship, especially if she is defecting for another mate.

Men's Violence Against Female Partners: The Role of Culture

Barbara Krahé

University of Potsdam, Potsdam, Germany

Synonyms

Domestic violence; Intimate partner violence; Relationship violence

Definition

Men's violence against female partners is defined as behavior that causes physical, sexual, or

psychological harm, including acts of physical aggression, sexual coercion, psychological abuse, and controlling behaviors. It has high prevalence rates worldwide, with about 30% of women aged 15 years and over likely to experience violence by an intimate partner in their lifetime. At the same time, rates vary substantially in relation to cultural variables, such as gender inequality, collectivism, societal approval of intimate partner violence, and honor concerns.

Introduction

Men's intimate partner violence (IPV) against women has high prevalence rates worldwide, with about 30% of women aged 15 years and over likely to experience IPV in their lifetime. At the same time, rates vary substantially between cultures. This article reviews current research findings on cross-cultural differences in the prevalence of men's IPV against women and discusses them in relation to culture-level variables, such as gender inequality, collectivism, societal approval of IPV, and honor concerns. These cultural context variables shape the attitudes and norms of individuals about gender relations and IPV. Further research has demonstrated interactive effects between culture-level and individual-level variables in predicting IPV. Challenges for cross-cultural research on IPV in the age of migration and the outline of a gender-inclusive approach to the study of IPV are discussed in the final section.

Men's Violence Against Intimate Partners: The Role of Culture

Across the world, women are at risk of experiencing aggression and violence by men with whom they are in an intimate relationship. IPV is defined as “behaviour by an intimate partner that causes physical, sexual or psychological harm, including acts of physical aggression, sexual coercion, psychological abuse and controlling behaviours” (World Health Organization 2013, p. vii). Although this definition is neutral with regard to

the gender of the victim and the perpetrator, the most common form is men's IPV against a female partner. The main method for studying the prevalence and impact of IPV is through women's self-reports of victimization in large-scale surveys, if possible drawn as a representative sample from the general population.

A comprehensive review of the prevalence rates of intimate partner violence in 81 countries revealed that globally in 2010, 30% of women from the age of 15 had experienced at least one incident of physical and/or sexual violence victimization by an intimate partner in their lifetime (Devries et al. 2013). Despite overwhelming evidence of the negative consequences for women's physical and psychological health and well-being (Coker et al. 2011; Martin et al. 2011), IPV is not uniformly condemned and penalized across the world. A study by the United Nations (UN) revealed that in 2011 no more than 125 out of 193 member countries of the UN outlawed domestic violence (Turquet et al. 2011). This figure means that in more than a third of the member states, women have no legal protection against IPV, and men do not have to fear criminal prosecution when acting violently against their female partner. In the next section, we will present data on the extent to which prevalence rates of IPV against women differ between countries and regions, followed by a review of the evidence on culture-level, societal factors linked to these differences.

Variations in the Prevalence of Men's IPV Between Countries

The most recent comprehensive review of the global prevalence of IPV was presented by Devries et al. (2013). They collected evidence from 151 original population-based studies from 81 countries to assess the lifetime prevalence rate of women's experience of physical and sexual victimization by an intimate partner from the age of 15 years onward. Only women who had ever been in a relationship were included in the calculations. In addition to establishing an overall prevalence rate of 30%, the review yielded specific

information about rates in different regions of the world, as shown in Fig. 1.

The review shows that prevalence rates of IPV victimization differ markedly between regions, with a difference of almost 40% between the lowest and the highest rates. It needs to be borne in mind that these figures are based on a large number of studies employing different definitions, designs, and methods, so part of the variability is likely to be due to methodological differences (see Krahé et al. 2005). Nevertheless, the figures clearly highlight the need to understand why women are at higher risk of experiencing IPV in some parts of the world than in others so that appropriate measure can be taken.

Looking at homicide as the most extreme form of IPV, a review of the evidence from 66 studies examined the proportion of killings committed by an intimate partner relative to the total number of killings (Stöckl et al. 2013). The results showed that almost 40% of all female homicide victims were killed by an intimate partner, whereas only 6% of killings of men were committed by an intimate partner. The proportion of intimate partner killings in the total number of homicides varied considerably between countries, ranging from about 15% to 60%.

Studies collecting primary data in several countries based on the same methodology also demonstrate substantial differences. A study with nearly 16,000 university students from 21 countries, who completed the Revised Conflict Tactics Scales (CTS2) as a measure of IPV, found rates of experiencing at least one act of physical assault by a dating partner in the last 12 months to range between 12% and 40%. The rates of sexual violence victimization ranged between 9% and 42% (Chan et al. 2008). A comparative study in 9 European countries with about 3,500 university students completing the same survey instrument in each country also revealed substantial differences in the prevalence of sexual violence victimization of female students by a male partner, with rates ranging between 11% and 33% (Krahé et al. 2015). In combination, empirical evidence clearly points to the role of cultural factors in the search for explanations of differences in the level of IPV.

Men's Violence Against Female Partners: The Role of Culture,

Fig. 1 Lifetime percentage of IPV victimization in ever-partnered women aged 15 or over in 20 regions comprising 81 countries (based on Devries et al. 2013)

The Role of Culture in Explaining Men's Violence Against Intimate Partners

Explanations of men's violent behavior against an intimate partner address the macro level of the culture in which they live, the micro level of dyadic interaction patterns between the partners, and the individual level of the aggressor. Although they can be distinguished for analytical purposes, these levels are closely interconnected because cultural norms and conditions also shape interactions within the couple relationship and the attitudes and behavior of individual perpetrators.

Culture-level theories consider causes of IPV that lie in the social structure and value systems of a culture, whereby culture can be a nation or a

particular social group defined by regional traditions, religious beliefs, or other aspects. A critical social-structural variable relevant to IPV is the extent to which a culture is characterized by a *patriarchal power hierarchy* that assigns men a superior status over women (Bartholomew et al. 2015). This power imbalance to the disadvantage of women is seen to permeate not only a wide range of public domains but also the private domain of intimate relationships. The shared view that men are entitled to wield power over women implies that men have the right to expect their female partners to fulfil their demands and expectations and to penalize them if they fail or refuse to do so. The unwillingness to acknowledge marital rape as a criminal offense, which is

still common in many parts of the world, also reflects the understanding that men acquire possession of women with marriage. Several indicators have been developed at a global scale to characterize cultures (mostly defined by national boundaries) in terms of gender equality or inequality. Examples are the Gender Inequality Index (GII) by the United Nations Development Programme, <http://hdr.undp.org/en/content/gender-inequality-index-gii>; the Social Institutions and Gender Index (SIGI) by the OECD, <https://www.genderindex.org/>; or the Gender Equality Index of the European Institute for Gender Equality (EIGE), <http://eige.europa.eu/gender-equality-index/about>.). These indices include access of women to higher education and health, representation of women in senior political positions or leading managerial positions, or entitlement to inheritance and other resources.

To provide empirical support for this line of explanation, studies have related country-level indicators of gender (in)equality to differences in IPV between countries, predicting a negative correlation between gender equality and IPV rates. Based on data from 44 countries representing almost 500,000 women, a significant association was found between women's physical or sexual IPV victimization in the past 12 months and the extent to which women's equal access to land, property, and other productive resources was restricted by law and practice compared to men (Heise and Kotsadam 2015). Moreover, these authors found a significant positive association between the collective acceptance of norms justifying wife beating and norms of male authority and rate of men's IPV across the included countries. These findings suggest that reducing the gender inequality in access to financial resources might be a successful way of strengthening women's independence from men, thereby decreasing their risk of IPV. Microfinance programs that give small-scale loans to women have been introduced in this vein, but systematic research on their effectiveness in reducing IPV has so far been limited and inconclusive (O'Malley and Burke 2017).

Research comparing victimization rates of women against those of men across cultures

further supports the role of gender inequality as a facilitating factor for men's IPV. A study including victimization rates in 16 countries showed that the less power women had in the respective country, the higher women's victimization rates were compared to those of men (Archer 2006).

The same analysis also revealed that women's IPV victimization rates went up compared to men's the more countries were at the collectivism end of Hofstede's (1980) dimension of individualism-collectivism. This dimension describes the extent to which a culture values community goals and ties higher than individual characteristics and autonomy. Because differentiations into ingroup and outgroup members are more relevant in collectivist cultures, it could be argued that intimate partners brought into a man's family are seen as outgroup members who are supposed to follow the family rules. The finding that the gap between rates of female relative to male victimization widens the more a country scores toward the collectivist end of the continuum is consistent with this line of reasoning (Archer 2006).

A further culture-level variable shown to relate to men's IPV perpetration is the emphasis on male honor and the rights granted to men for ensuring their female partners obey the rules of the honor code. This line of research originated in the United States and links higher rates of violence, especially IPV, to cultural differences between the northern states of the United States on the one side and the southern states as well as Latin America on the other. Specifically, the strong emphasis on honor in the southern states and Latin American led Vandello and Cohen (2003, 2008) to identify a "southern culture of honor" in which honor is a salient theme for organizing manhood and gender relations. Honor is defined by status and reputation and – when threatened – may legitimately be restored and defended through the use of violence. In honor cultures, men's standing is critically defined by their toughness, ability to protect their family and possession, and their partners' adherence to accepted standards of female decency. If men see their partner as violating the honor code, violence is legitimate and even imperative in an honor culture to preserve the integrity

of the men and their family. In several studies, individuals from honor cultures were found to be more accepting of men's IPV than those from non-honor cultures, indicating that cultural constructions of manhood and female decency may create a social climate that legitimizes IPV.

Gender inequality and constructions of manhood at the cultural level are the socially shared background that shapes the attitudes of individuals in the course of socialization. Attitudes about gender and violence, in turn, provide a basis for violent behavior toward an intimate partner. An analysis of 52 studies assessing individual attitudes relevant to IPV found that hostile sexism (negative attitudes about women; Glick and Fiske 1996) and the endorsement of traditional gender roles by both men and women were higher in countries with lower gender equality at the macro level. The same was true for men's approval of slapping a partner, whereas women's approval of slapping a partner was unrelated to IPV rates (Archer 2006). Using data from a nationally representative survey in 41 countries in Eastern Europe, Africa, Asia, Central and South America, and the Caribbean, Hayes and Boyd (2017) found that the higher the country-level justification of IPV, the more likely individual participants were to find physical violence justified in different scenarios.

These individual differences in attitudes, shaped by cultural context, play a significant role in understanding individual differences in the propensity to engage in IPV. In the multilevel analysis by Heise and Kotsadam (2015), higher individual endorsement of the belief that men's authority over women is legitimate was found to be related to an increased odds of experiencing IPV over and above the collective acceptance of this belief at the country level. Furthermore, the multilevel approach enabled the authors to show that individual-level variables had a differential impact on IPV risk depending on country-level variables: In countries with a high acceptance of IPV and men's authority over women, spending between 8 and 11 years in education showed a significant negative correlation with IPV, suggesting that education may reduce the risk of IPV. In countries low in acceptance of these

gender inequality norms, the association was nonsignificant.

Adopting a similar approach, a meta-analysis by Mallory et al. (2016) examined the impact of risk markers of IPV at the individual level on the probability of women's IPV victimization in three groups of countries: the United States, as a country ranking high on the individualism dimension as determined by Hofstede et al. (2010), individualist countries other than the United States, and collectivist countries. Of the 11 risk markers considered in their analysis, only 4 differed between the 3 groups of countries: Witnessing parental violence and experiencing emotional abuse in a relationship were more closely linked to IPV victimization in collectivist countries. Younger age and lower marital satisfaction were more closely linked to IPV victimization in the United States than in the other two groups. These findings show that culture and individual characteristics interact in predicting IPV.

Challenges to the Link Between Culture and IPV in the Age of Migration

The research reviewed in this article has provided ample evidence that men's violence against intimate partners, while being a worldwide problem, shows considerable variation between countries and cultural groups. The evidence discussed in this article has illustrated how differences in the way gender relations are organized at the macro level of cultures, such as gender equality, collectivist values, and concerns about honor, relate to differences in the scale of IPV and also shape the attitudes and behavior of individual perpetrators.

In a time that sees migration on a large scale, the evidence of close connections between cultural factors and individual attitudes and behavior relevant to IPV raises a pressing question for research and social politics alike: What happens when individuals socialized in a cultural context with a higher tolerance of gender inequality and IPV move to less tolerant cultures with more egalitarian value systems? How do societies cope with a clash of incompatible constructions of gender relations, including men's dominance

over women, and approval of IPV, and how do individuals moving into a new culture position themselves to the different social norms they encounter? What happens to power relations within couples if women adopt the egalitarian views and opportunities afforded to them in their host society, challenging their partners' traditional conceptualization of manhood?

Evidence suggest that the renegotiation and reevaluation of attitudes and behaviors related to gender roles and IPV that is required by couples in these circumstances may precipitate violent responses as a way of asserting masculinity (White and Satyen 2015). These challenges add to the other stressors involved in the acculturation process that may, in themselves, lower the threshold for IPV. Future studies of IPV among refugees and immigrants therefore need to examine reactions to the clash of norms and attitudes between the culture of origin and the host culture and their role in understanding IPV.

Outlook: A Gender-Inclusive Approach to the Study of IPV in its Cultural Context

In line with the focus of this contribution on contexts for men's aggression against women, only research considering men as perpetrators and women as victims of IPV was discussed. However, it is important to note that women also engage in IPV against male partners, as shown by a substantial body of research (Archer 2018; Swan et al. 2018), even though it has been suggested that women more often engage in reactive forms of self-defense than in proactive forms of coercive control. This research has been conducted almost exclusively in Western countries, leaving the role of cultural variables largely unaddressed. First evidence of the cross-gender impact of power equality comes from a study with university students from 20 countries and showed that male victimization rates were higher the higher social status of women was in the respective country (Hines 2007). However, a different pattern emerged in later studies including nine European countries, which found that male victimization rates were

lower the higher the gender equality in the domain of political participation (Krahé et al. 2015). Finally, it is increasingly recognized that IPV is also a problem in same-sex relationships, with some studies suggesting higher prevalence rates and a more negative impact than for heterosexual relationships (Messinger 2011; Gehring and Vaske 2017). Again, the vast majority of studies addressing the risk of IPV in sexual minorities comes from North America and Western Europe, and the fact that same-sex relationships are still prohibited in many parts of the world raises problems regarding the cross-cultural analysis of IPV in same-sex relationships.

In combination, these developments highlight the need to broaden the scope of our conceptualization of IPV, moving beyond a purely behavioral analysis of IPV to consider its underlying motivation and function, and to develop more comprehensive theoretical explanations that can accommodate both male and female IPV in heterosexual and same-sex relationships. Such explanations are vital to design effective forms of prevention and intervention to reduce IPV and the associated serious physical and mental health consequences in all victims regardless of gender and sexual orientation.

Menarche

Theresa E. Jackson
Bridgewater State University,
Bridgewater, MA, USA

Synonyms

First “period”; First menstruation; Onset of menstruation

Definition

The initial onset of menstruation for a woman, usually occurring during early adolescence.

Introduction

Menarche, or the first menstruation, is a concrete developmental milestone that occurs suddenly and often unexpectedly. It is considered the culmination of pubertal events for young girls, though other gradual sex differentiation continues to occur throughout adolescence. Menarche represents a physiological transition since it establishes girls' reproductive capacity, yet it is also imbued with sociocultural significance and personal meaning. The timing of menarche is influenced by several genetic, biological, and

environmental factors, and much research has shown that both timing and preparation have an effect on girls' attitudes toward menarche.

Onset, Trends, and Timing of Menarche

Menarche is often the last and is considered the most climatic pubertal event for girls, occurring roughly 2 years after the beginning of other pubertal changes. Currently, in the United States, the average age of menarche is approximately 12.5 years, with a range of 10–14 years considered to be a “normal” age at which to reach menarche. Several studies have indicated that African American girls reach menarche up to 8 months earlier than White and Mexican American girls (Chumlea et al. 2003), while other studies have revealed that Latina girls reach menarche earlier than both White and African American girls (Obeidallah et al. 2000). However, most ethnic differences disappear when low SES, conceptualized as an environmental stressor leading to early puberty, is controlled for.

These average ages represent a significant decline over the past several centuries, where the age of menarche fell from 17 years in the mid-1800s to 13 years in the 1950s. Since the 1950s, the average age has continued to decline, but at a much slower, steadier rate, and with a greater increase in ethnic disparities noted above. It is posited that the drastic changes observed over the past century and a half are likely due to improvements in nutrition, sanitation, and treatment of infectious disease (Posner 2006). The slighter changes since the 1950s are thought to be due to continued changes in diet, leading to increased obesity, and earlier exposure to stressful environmental circumstances (Kaplowitz et al. 2001).

The exact triggering mechanism for menarche is unknown; however, the production and secretion of gonadotropin-releasing hormone (GnRH) by the hypothalamus is essential for the initiation of puberty more broadly. There are three widely accepted categories of influence on individual

differences in timing of menarche that interact in a complicated fashion: (1) heredity and genetics, (2) biological factors, and (3) environmental factors.

Heredity

Researchers have historically observed hereditary influence on menarcheal age through assessing correlations between mother and daughter age at menarche. Indeed, such studies have revealed small to moderate positive correlations, though critics have argued that shared environmental influences could account for the observance of such relationships (Graber et al. 1995). Studies seeking to identify particular genes influencing menarcheal age have not yielded conclusive results, indicating that specific genetic contributions remain unknown. However, twin studies also reveal a higher correlation for menarcheal age among monozygotic twins than dizygotic twins (Mendle et al. 2006), and thus, it is still widely accepted that genetics and heredity do account for at least *some* of the variability in menarcheal age (Karapanou and Papadimitriou 2010).

Biological Factors

There are two primary theories relating the triggering of menarche to physical growth. The skeletal growth hypothesis suggests that a girl must reach a particular level of musculoskeletal development in order to reproduce. Specifically, her pelvis must be large enough to bear children. Support for this theory arises from data indicating that most girls who have reached menarche have also achieved a pelvic diameter of at least 26.2 cm (Ellison 1982). The accumulated body fat hypothesis suggests that girls must reach a critical BMI and maintain a certain level of body fat in order to begin and continue menstruation as well as ovulation. It was originally developed by Frisch (1983), who proposed that girls must be capable of sustaining their own health prior to attempting to bear children. This hypothesis suggests that the link between body fat and the initiation of menarche is the hormone leptin. Leptin is largely produced by brown adipose (fat) tissue, and it acts as a signal telling the

hypothalamus to begin secreting GnRH once this critical level of body fat has been accumulated (Allison and Hyde 2013). Support for this theory arises from several indicators, including higher leptin levels in children with higher BMIs, delayed menarche in competitive athletes, and the cessation of menstruation in competitive athletes and anorectics who have a low BMI (Graber et al. 1995).

Environmental Factors

While it has long been accepted that genetic and biological factors affect menarcheal timing, other researchers have proposed more inclusive models taking into consideration the interaction of environmental influences and biology. Perhaps the most popularized and controversial model investigates the role of father absence (sometimes conceptualized as family disruption) on early puberty. Father, but not mother, absence has been consistently associated with earlier menarche; however, the exact mechanisms and reasons for this association have been contested (Moffitt et al. 1992). It is posited by sociobiological theories that father absence triggers early puberty in girls as an adaptive response to a stressful environment, where girls mature earlier in preparation for earlier reproduction in order to ensure the continuation of their gene pool (Belsky et al. 1991; Posner 2006). Paternal investment theory further suggests that girls encode information from their early environments into mechanisms that will influence their later sexual development. Girls growing up in a father-absent home recognize that paternal investment is not necessary for reproduction, and they are hypothesized to mature more quickly, begin sexual activity earlier, and orient to more disruptive child-rearing environments, i.e., unstable relationships with male partners. Some have argued that environmental confounds such as weight, nutrition, and stressful life situations or events have not been controlled for in investigations into the role of father absence in early menarche (Posner 2006). Indeed, a strong relationship between low SES, often conflated with father absence, and early puberty is continuously reaffirmed (e.g., Allison and Hyde 2013). Thus, it is difficult to determine whether it is

father absence per se or a stressful rearing environment more broadly that is leading to early menarche.

Psychosocial and Physiological Effects of Menarche

While other pubertal changes such as breast and pubic hair growth occur gradually and continuously throughout pre- and early-adolescence, menarche is unique in that it occurs suddenly and often unexpectedly. Indeed, many girls report feeling shocked, surprised, or confused at menarche, and this reaction can be magnified in particular among girls who are considered to be early maturers. The literature defines early maturers according to two different metrics: objective and subjective timing. Furthermore, there is not exact agreement as to what constitutes objective early menarche, though most define it as occurring before the age of 11 (Nnoaham et al. 2012). Subjective timing refers to the perception of being “on time” with one’s peers and is perhaps more important when considering the psychological ramifications of early menarche and puberty more broadly (Stubbs 2008).

Early objective timing has implications for a girl’s level of preparedness for menarche, both in terms of knowledge and developmental stage. It has been repeatedly reported in the literature that more preparation for and knowledge of menarche is associated with fewer negative attitudes and less overall worry about menstruation (Cooper and Koch 2007; Stubbs 2008). If girls reach menarche objectively early, then they are at risk for not having adequate preparation or knowledge, missing the education occurring in schools, from family members such as mothers or older sisters, and from peers. Furthermore, it has also been hypothesized that early menarche can lead to a gap between physical maturity and the accompanying psychosocial maturity necessary for facing the challenges and stress brought on by these developments. Peers and adults alike may attribute greater psychosocial maturity and responsibility to physically mature girls, suggesting that they meet new norms and expectations for their

behavior before they are emotionally or cognitively ready (Mendle et al. 2006).

Indeed, there has been a great deal of research suggesting that early maturers are at increased risk for developing a negative body image, disordered eating, and depression (Stice et al. 2001). Explanations for these associations are complex and vary by study, but most ascribe meaning to the changes in social context that accompany menstruation. Girls experiencing early menarche also experience outwardly visible changes to their bodies such as breast development, growth of the musculoskeletal system, and increases in adipose tissue. Experiencing these changes prior to one’s peers can be isolating and alienating and can increase negative social pressure. Early maturing girls often seek out peers who appear outwardly similar to them but are much older in chronological age (Natsuaki et al. 2011), putting them at risk for engaging in behaviors they are not psychologically prepared for from a developmental perspective. It has also been theorized that early increases in fat tissue can make it difficult for girls to fit western cultural standards and ideals for feminine appearance, creating a risk for negative body image early in life. Heightened negative body image is then thought to contribute to eating disordered behavior as girls try to minimize their dissatisfaction with their bodies through engaging in weight-controlling behaviors such as dieting and purging (Stice et al. 2001).

Attitudes Toward Menarche

In general, researchers have observed girls’ attitudes toward and women’s recollections of menarche to be largely negative across socio-cultural contexts. Many girls report feeling shame, embarrassment, confusion, and fear upon seeing menstrual blood for the first time (Lee 2008; Stubbs 2008). Recent studies have revealed that girls in the USA may be meeting menarche with more ambivalence than previously observed, in part as a result of the emergence of more girls and women who are challenging predominantly negative social scripts about menstruation and the body (Lee 2008).

Investigations into how social context and identities might affect attitudes toward menarche have revealed interesting and at times mixed results. While most studies report more negative reactions among black and working-class participants (Cooper and Koch 2007), Martin (1987) observed that her sample of black, working-class participants reported experiencing menarche simply as a life change to be dealt with in private rather than a hygienic crisis. Investigations into Mexican women's recollections of menarche indicate that many reacted with more ambivalence and confusion, though some older generations who knew of menarche prior to its onset recalled positive emotions (Marvan et al. 2006). Fahs (2011) has observed that lesbian and bisexual women recount more positive experiences and the provision of support around menstruation, potentially leading to the transmission of more positive emotions and attitudes among these communities of women.

Conclusion

Menarche is an important event from a biological and social perspective as it prepares a girl's body for reproduction and carries sociocultural meaning. A complex interaction of genetic, biological, and environmental factors contributes to menarcheal age, and a girl's age at menarche can have significant developmental implications, particularly if it occurs early. Societal attitudes toward menarche remain largely negative, though girls have begun to report reacting to it with more ambivalence. Further investigating factors that can trigger early menarche and lead to the maintenance of negative attitudes toward it is imperative as we seek to aid adolescents in their transition to adulthood.

Mendel's laws; Mendelian inheritance; Plant hybridization

Definition

It is well known that Charles Darwin published his theory of evolution in his 1859 book *On the Origin of Species by Means of Natural Selection*. One of the fundamental problems with Darwinism was the absence of an explanatory mechanism of inheritance that could account for morphological change. In 1868, Darwin would explain the mechanism in his book *The Variation of Plants and Animals under Domestication*. He called it theory of pangenesis. Around the same time, the monk Gregor Mendel

was working on a similar line of research. He was studying the inheritance of characters by experimenting on pea hybrids. Mendel, who published his results in 1866, asserted that resolving the inheritance problem was fundamental to understand the evolutionary history of organic forms. Mendel's research revolutionized the concept of inheritance, but it was disregarded by his contemporaries. However, by 1900, the laws of Mendelian inheritance would be rediscovered, leading to the birth of the field of genetics. How did he do it?

Introduction

In 1843, Johann Mendel (Gregor would become his monastic name) joined, as a novice, the Augustinian Abbey of Saint Thomas, which is in the present-day city of Brno in the Czech Republic. He was 21 years old. Young and without resources, he became a friar to continue his education. First things first, he had to be ordained as a priest, then he could follow the Augustinian motto: through knowledge to wisdom. At the University of Vienna, he studied physics, chemistry, mathematics, zoology, and botany. He had good teachers, such as the experimental physicist Christian Doppler, the mathematician Andreas Ettinghausen, the chemist Josef Redtenbacher, and in particular, the brilliant botanist Franz Unger. The last was an expert in plant physiology and a proponent of the cell theory. Gregor did not forget his teachings on plant fertilization. In short, in Vienna, he learned how to use experimental and quantitative methods in biology.

In 1853, Mendel returns to the monastery. Encouraged by the abbot Franz Cyrill Napp, he devotes himself to horticulture. After 3 years, Brother Gregor begins experimenting with peas. In the spring, he prepares the ground to pick the harvest in summer. During flowering, he manipulates the pistil, depositing previously selected pollen. He studied floral arrangement, plant size, and color and shape of pods and seeds. He examined in total around 30,000 samples. On the afternoon of February 8, 1865, Mendel presents the results of his research at the Brno Natural History Society. By March 8, he would complete his task. He

spoke of the uniformity of the first hybrid generation, the segregation of characters in the second generation, and the independent transmission of characters. The lectures were dry. The audience did not understand Mendel's principles. It was on a rare theme with a mathematical format that obscured the presentation. The work was published in the Society's journal in 1866. Two years later, he was elevated to abbot. He dedicated himself to the governing of the monastery, and as a result, his scientific activity declined. However, he continued to experiment until the 1870s, particularly on plants of the genus *Hieracium* (common name hawkweed). The abbot died suddenly on Three Kings' Day (January 6) in 1884 as he was busily attending to his religious work.

On Tuesday, May 8, 1900, the renowned English biologist William Bateson heads to the Liverpool Royal Horticultural Society to give a lecture on the problems of inheritance in horticulture. He travels by train. During the journey, he reads Mendel's article. By the time that he arrives at Liverpool Street station, his concept of inheritance has changed. Bateson understood the positive significance that Mendel's theory had on his model of discontinuous evolution. He accepted it immediately by disseminating and duplicating the approach (1900, 1902, 1909). Within a few years, a new knowledge, which Bateson called genetics, was formed. Mendel would be its patriarch (Bowler 1989; Henig 2000).

The Experiments

The pea, *Pisum sativum*, was a common species studied by well-known horticulturists such as Thomas Knight, John Goss, Alexander Seton, and Carl Gärtner. It was an ideal plant due to its simple cultivation, the presence of constant and recognizable characters, and the existence of a particular floral arrangement that inhibited pollen contamination. Mendel's selection was not novel. Neither were his observations. The dominance, morphological constancy, and segregation of characters were previously known phenomena. Mendel's originality laid in his differing

interpretation of the observations, which were underlined by his statistical analysis of phenotype and the subsequent conceptual development of genotype.

In 1856, Mendel began his experiments on pea hybrids. The objective is to study how different morphological traits are inherited. He obtained 34 varieties, which he experimented on for over 2 years to determine typological constancy. He selected 22 conserved and invariants lines, and differentiated seven pairs of opposing characters: (1) the round or wrinkled shape of the seeds; (2) the yellow or green color of the seeds; (3) the grey or white color of the seed coat; (4) the smooth or ridged shape of the mature pods; (5) the green or yellow color of the immature pods; (6) the axial or terminal arrangement of the flowers (on the stem or at the end); and (7) the height of the plant (tall or short). He established seven groups of experiments corresponding to each morphological pair. By means of artificial fertilization, he performed reciprocal crosses. That is, in successive fertilizations, he alternated each plant as the egg or the pollen donor. In the first hybrid generation (F1), the individuals are morphologically constant, expressing only one of the characters (the dominant one). The other one (recessive) remains latent. For example, the round seed shape is dominant over the wrinkled one. The phenomenon occurs regardless of whether the dominant trait belongs to the pollen or to the egg donor plant. Moreover, Mendel did not observe intermediate forms. Crossing F1 individuals resulted in the second generation (F2), which showed a dominant to recessive phenotypic ratio of 3:1. Subsequent crosses of F2 individuals determined the actual proportions corresponding to the Mendelian expression $A:2A:a$, that is, a pure dominant individual (homozygous) to two dominant hybrids (heterozygous) to a pure recessive individual (homozygous). The second part of the experiment consisted of crossing plants that carried different traits for the various characters. The results coincided as proven by the independent segregation of the characters. Mendel repeated the study with other plant species to verify the universal value of the laws observed

in *Pisum*. In particular, he used plants of the genus *Phaseolus*: the beans. The hybrids of *Ph. vulgaris* and *Ph. nanus* fully reflected the expected results. However, with *Ph. multiflorus*, the color of the flowers and seeds of the F1 generation were different: they did not show dominance and were distinct from the parental traits. Mendel presumed that tonality in *Ph. multiflorus* was due to the combination of uniformly expressed autonomous colors. In the hybrid, each color was freely combining to modify the coloration. He solved the dilemma by assuming that the anomaly reflected a pea-like combinatorial dominance/recessiveness by interpreting each color as an independent trait.

After publishing the results, Mendel continued his experimental work by collaborating with Carl Nägeli, a prestigious Swiss botanist and a professor at the University of Munich. The professor rejected the validity of Mendel's theory of inheritance but agreed to send him *Hieracium* plants and seeds for experimentation. In the 1869 proceedings of the Brno Natural History Society, Mendel presented his first findings. Mendel had failed. The hybrids did not replicate the hereditary process of the peas. Why? Nowadays, we know the reason: the plant usually reproduces asexually (apomixis). The seed, therefore, has an exclusive maternal origin. As a result, the offspring replicate the mother plant. *Hieracium* is an impossible example to study the dominance and segregation of characters. Nägeli had been working with *Hieracium* for a long time and knew the experimental difficulties of the plant. Was he intentionally seeking to impede Mendel? Suspicion is admissible.

For one reason or another, Mendelian experiments provoked controversy. However, the case of Ronald Fisher is exceptional. In 1936, the English geneticist published an article in the journal *Annals of Science* entitled *Has Mendel's work been rediscovered?* Fisher had thoroughly analyzed Mendel's experimental structure and found that the observed ratios were higher than expected according to sampling theory. Based on this fact, Fisher argued that much of the experimental decisions taken by Mendel were intelligible only if the theory had been formulated a priori. That is,

Mendel's intention would have been to demonstrate experimentally the validity of a theory that was elaborated in the abstract. Did the monk arrange the experiments to prove it? During the first decades of the twentieth century, biologists such as Carl Correns, Erich Tschermak, William Bateson, and Robert Lock repeated the experiments (Johannsen 1926). To a greater or lesser extent, the results all corroborated Mendel's data – Tschermak even obtained more precise percentages. Do these results invalidate Fisher's criticism? Absolutely not. They say nothing about Mendel's intention, just that his experimental method was correct. As the American geneticist Alfred Sturtevant argued, we can attribute the stochastic event to different fortuitous but not completely satisfactory facts (1965). There is only one irrefutable answer: *Mendel was right*. He made a big step in the right direction.

Biological Mechanism

With the inheritance problem solved, the next task was to explain the biological mechanism underlying it. Mendel interpreted it as a simple division process typical of cells in the ovary and pollen. Traits for each character would be determined by individual factors located in the gametes. These factors come together during fertilization, giving the embryo several of the traits of each character whose morphological expression follows the principle of dominance and recessiveness. Gametogenesis, or the formation of gametes, was a crucial process that again separated the factors that united during fertilization. In this simple way, all of the individual morphological potential is again available to the next generation. Implicitly, from these ideas developed the modern concepts of gene, allele, phenotype, and genotype, all of which are, necessarily, rooted in cell theory. Gametes would be the cells characterized by their particular hereditary function, defining two clearly differentiated cell lines: germline and somatic (Galera 2000).

Under the Mendelian approach, hybrids represent reproductive variability. Logically, they are

the cause of speciation. How does this happen? Mendel supported his hypothesis based on the experiments on hybrid stability developed mainly by Carl Gortner, who worked on plants of the genera *Aquilegia*, *Lavatera*, *Geum*, *Dianthus*, and *Oenothera*. Speciation occurs when the hybrid form becomes stable by invariably transmitting its typology to all offspring. A new species then appears. What is the biological meaning? Mendel imagines that stabilized hybrids are formed by the fusion of complementary gametes whose union is permanent. In other words, fertilization brings together the parental traits into a new factor that has its own morphological value that is inseparable during gametogenesis. Individuals, then, only produce gametes of the new hybrid type. If the gametes are not complementary, the hybrid has a transient value, and the parental traits will segregate normally and reappear in subsequent generations (Galera 2000).

Conclusion

Mendel solved the problem of inheritance in the context of the Darwinian theory of evolution. He did so by applying new ideas to known facts and using the experimental and quantitative method. The results are known as Mendel's laws, which form the basis of modern genetics. The evolutionary meaning of these laws is clear: cross fertilization and hybridization manifest an unequivocal tendency to preserve parental types. It is, therefore, an inadequate mechanism to govern the evolution of species under the terms proposed by Darwin. According to Mendelian ideology, chance is responsible for combining parental characters and fixing them in hybrids as pure species, and speciation is a discontinuous biological phenomenon resulting from reproduction. Mendel's laws represent an alternative evolutionary standard, directly linked to the neo-Darwinism of August Weismann and included by Hugo de Vries in his theory of mutation. Certainly, William Bateson had gave reasons to think that evolutionism would have had a different history if Charles

Darwin had been familiar with Mendel's work (1909). It could be that Bateson was wrong, since probably Darwin knew the monk's research (Vorzimmer 1968).

Menopause

Susanne Röder

University of Bamberg, Bamberg, Germany

Synonyms

Climacterium; End of Reproductive Ability; Post-reproductive Life Span

Definition

The biological definition of menopause refers to the irreversible loss of the physiological capacity to produce offspring due to intrinsic biological factors. The term menopause is colloquially used as synonym for the post-reproductive life span in females of all species and covers the life period between the end of reproductive ability and the end of life.

Introduction

Menopause is quite the opposite of menarche. In its broadest sense it refers to the time period when female's ability to reproduce (to bear a child) stops permanently and females no longer have menstrual periods and can no longer become pregnant. The ability to bear children gradually declines throughout a female's reproductive life. This process is essentially caused by a decreased estrogen production of the ovaries. Even though the transition to menopause shows accessory symptoms like hot flashes, mood changes, or an increase in heart diseases, it is a physiological and natural change that concerns all females across all species. When the post-reproductive life span of human females is compared to most other species something different and unique is revealed; women exhibit a very long post-reproductive life span whereas most animals reproduce almost until they die. Even if the proximal causes of menopause are well understood the evolutionary

(ultimate) causes remain still unclear and lead scientists to investigate finding possible answers to the question; why do women go through menopause at an age long before other body functions senesce? To date, some possible explanations to the evolution of menopause exist from which I summarized the most common in the following entry.

The Evolution of Menopause in Human Females

Evolutionary theories predict that selection should operate against living beyond the age of reproduction. Therefore, the observable decline in women's reproductive ability long before end of life seems puzzling. The reproductive ability (reproductive life span) of human females ends long before other body functions senesce (including for example cardiac function, breathing capacity, renal plasma flow, and vital capacity) and that makes – with just a few exceptions – human beings unique. The reproductive ability of women starts with the menarche, about the age of 15 years, and ends with the menopause, between the ages of 40 and 60 years (see Morabia and Constanza 1998; Gordon and Laufer 2005). Menarche and menopause are therefore the two major occurrences in women's reproductive life span due to the fact that they mark the beginning and the end of a woman's reproductive life span. The 10–15 years before menopause are characterized by declining fertility. Consequently, a human female's reproductive life span is compressed into only approximately 20 years of a longer (unfertile) biological life span whereas most other placental mammals (exempt from some primates) retain their fertility almost to the end of their life span (Pavelka and Fedigan 1991; Caro et al. 1995). Thus, compared to other species, human females experience a dramatic loss in ovarian function and subsequent menopause around the age of 50 years and they additionally spend a significant longer time of their life in an infertile state. The proximate cause of this loss of fertility is the cessation of ovulation attended by hormonal

changes in the neuroendocrine system and the advanced depletion of ovarian follicles (follicular depletion) with increasing age.

In most species such a prolonged post-reproductive life span is not observable and females die soon after the last reproductive event, which also demonstrates that a prolonged post-reproductive life span is normally rare. In general, the post-reproductive life period lasts only about 10% of the total life span (i.e., Jones 1975). In addition to some species like elephants, tortoises, and whales, females also experience menopause between the ages of 30 and 40 years, but after menopause their life span is with nearly 14 years, substantially shorter than the remaining time of humans (i.e., Marsh and Kasuya 1984). As a function of general senescence, a decline in age-specific fertility in later life is although common throughout all species, but a significantly prolonged post-reproductive life span as it is the case in human females seems unique. Therefore, menopause is a synonym for a prolonged post-reproductive life span that comprises the period of life between the end of fertility and the end of life (for a review see Levitis and Bingaman Lackey 2011). But why does human female fertility end up by menopause at an age long before general senescence makes gestations biologically impossible?

If menopause can be evolutionary explained in terms of an adaptation, it is necessary that any possible fitness advantages that come along with a shortened reproductive life span outperform any possible disadvantages. Evolutionary psychologists propose that menopause like other observable complex designed characteristics of individuals is, based on the Darwinian logic, the result of natural selection and can be considered as an adaptation. Darwin suggested that individuals should end up with physical and behavioral characteristics that allow them to perform well in the struggle of life in terms of competing with their rivals, finding food, avoiding predators, and, of course, finding a mate. Evolution therefore should have favored ancestors displaying these characteristics that ensure survival and reproduction and in return not allow extravagances or waste. An

essential test for the assumption that menopause is an adaptation shaped throughout evolution could be that it makes quantitative sense and results indeed in increased fitness (higher reproductive success).

It is also important to note that relative to the expected life span a shorter reproductive life span is only characteristic and observable for women, whereas male fertility remains high until the late fifties or early sixties (El-Faedy and Bean 1987; Hill and Hurtado 1991; Irons 1979). Men's reproductive ability additionally does not show a significant decrease up to other body functions also begin to senesce (i.e., Goldman and Montgomery 1989), and the estimated risk of reproductive cessation due to biological causes are also very different between women and men. In contrast to women, men's infertility (impotence) rises very gradually after the age of 50 years, whereas women's infertility rises very sharply between the ages of 40 and 50 years (i.e., Wood 1994).

Physiology of Menopause

Physiologically, menopause is also known as the climacteric and defined as the permanent absence of menses due to the ever-decreasing number of viable oocytes that are obligatory to maintain the hormonal cycle of normal female reproduction (Leidy 1994; Utian 2004). Human females produce their whole oocytes (approximately seven millions) they will have throughout life span already during the fifth month of gestation. A phenomenon that is only observable in female birds and female mammals. At birth the number of oocytes (follicles) is reduced to two million and declines furthermore to only 400,000 of the originally produced oocytes until the age of puberty. Approximately 1,000 oocytes remain at the onset of menopause (i.e., Faddy and Gosden 1996). This reduction of oocytes is caused by a programmed process of cell death induced by hormone withdrawal and is known as atresia (i.e., Gosden and Spears 1997). In the western world menopause typically occurs around the average age of 50 years and is medically defined as the absence of any vaginal bleeding for at least 12 consecutive months caused by the decrease in

hormone production by the ovaries. The transition from the reproductive life span to the post-reproductive life span is a natural change and not (usually) a disease or disorder induced by the natural depletion of the limited amount of oocytes (ovarian reserve), and associated with the natural occurring aging process (Fig. 1).

The process of ovarian aging (reproductive aging) is dominated by a gradual decrease in quantity and quality of the oocytes within the ovarian cortex and involves endocrine changes. Natural fertility gradually decreases from the mean age of 30 years onward because of the ongoing reduction of follicle numbers caused by ovulation and atresia. The first subtle clinical signs of the advancement of reproductive aging are the onset of cycle irregularities as insufficient availability of follicles leads to prolonged or shortened intervals of menstrual cycles and missed periods. The onset of this menopausal transition period (the period encompassing several years before the final menstrual cycle) occurs on average at the age of 46 years, with a range of 34–54 years. The main causes of the irregular cycles, and therefore the ongoing loss of reproductive ability, are an increase of the two circulating hormones: follicle-stimulating hormone (FSH) and luteinizing hormone (LH), due to the reduction of estrogen producing oocytes and follicles that are normally responding to these hormones. Menstrual cycles persistently become more and more irregular, varying in length from cycle to cycle and complete cycles were skipped.

Periods of amenorrhea (absence of menstrual cycles) of 60 or more days occur. Ultimately, the final cessation of menses (last menstrual cycle followed by 12 consecutive month of amenorrhea (onset of menopause) occurs at an average age of 51 years with a range of variation between age of 40 and 60 years. Even though a small number of follicles remain and estrogen continues to be produced (after menopause) in other tissues, like ovaries and fat tissues, this substantial smaller amount is not sufficient enough to maintain a women's reproductive ability.

Factors possibly affecting the age variations of onset of menopause are until now poorly understood. However, it has been suggested that environmental factors as well as lifestyle factors such as the use of oral contraceptives, parity, and smoking are possibly related to the age of onset. Tobacco smoking for example has been identified to advance the onset of menopause by about 2 years. Additionally, there is little information on possible genetic influences on the timing of menopause as positive correlations between age of mothers and daughters and also between sisters have been found (Murabito et al. 2005). To get further knowledge on the factors that affect the age of onset of menopause is also important from a medical point of view, as it has been found that early menopause is associated with a higher risk of cardiovascular diseases, osteoporosis, and ovarian cancer, and later menopause is attended by a higher probability to come down with endometrial and breast cancer.

Menopause, Fig. 1 Schematic representation of a female reproductive life span

Possible Explanations Why Menopause Has Evolved

Regardless of the precise mechanism, evolutionary theory generally predicts that there should be no selection for living beyond reproductive capacity (Williams 1957; Hamilton 1966). The fact that human females show a prolonged post-reproductive lifespan indicates an evolutionary dilemma and makes possible explanations of menopause somewhat confusing. If natural selection favors those individuals who leave the highest number of viable offspring, for what reason selection has not simply favored ancestors with higher numbers of initial oocytes or those with a slower rate of oocyte degradation or some other mechanism that would prolong reproductive ability instead of prolong reproductive inability? To date, many possible approaches exist about how and why menopause (prolonged post-reproductive life span) has evolved and the evidences are mixed. The two most common proposed hypotheses for the origin of menopause are (i) a change in investment in grandchildren rather than in further own children and (ii) a physiological trade-off between early fecundity and increased longevity. In the following sections you can find a summary of these two theoretical approaches, which perhaps can explain the origin of a prolonged post-reproductive life span in human females, termed menopause.

The Grandmother Hypothesis

The grandmother hypothesis is currently one of the most popular explanations for the evolution of menopause, which suggests menopause as an adaptation and refers to the increased inclusive fitness theory (Williams 1957; Hamilton 1966). It is known that being fertile until the end of life would not be beneficial because maternal risks increase with age. On the other hand, it is unknown whether a woman can gain their fitness (reproductive success) by extending their post-reproductive life span (Williams 1957). Thus, the grandmother hypothesis predicts that post-reproductive life span evolved because females can gain greater fitness by increasing the reproductive success of their own offspring (assisting their children to reproduce successfully) than by

continuing to reproduce themselves (Hawkes et al. 1998; Hawkes 2004). From then on, the benefit comes from increasing the reproductive success of their adult children and the survival of their grandchildren. In the animal kingdom this kind of support of post-reproductive “grandmothers” is mostly uncommon. Previous research on humans provides evidence that post-reproductive mothers can benefit from the reproductive output of their own offspring even though it has not been possible yet to test, whether prolonged post-reproductive longevity indeed can be associated with a higher number of grandchildren, because data covering the complete reproductive histories of several generations are related to the longevity of humans, are difficult to collect, and thus scarce. Most support for the grandmother hypothesis is based on empirical, multigenerational data sets (historical church registers) where all births, marriages, and deaths of each parish have been listed. Parishioners lived in historical rural communities during the eighteenth and nineteenth centuries (e.g., Lahdenperä et al. 2004) or in hunter-gatherer societies (e.g., Sear et al. 2000), where grandparents are known to be a significant part of the family by living in the same household, and together with at least one of their children plus grandchildren. These data sets show that grandparents assist their children by transferring knowledge, by giving a hand in their domestic tasks, and by supporting in child care, which all increase the nutrition and survival of the grandchildren. All are tasks that are known to positively affect the hypothesized offspring’s reproductive success.

Lahdenperä et al. (2004) investigated the fitness benefit effect of a post-reproductive life span by recording the survival and lifetime reproductive details of women (e.g., the number of marriages, number of children and grandchildren, age at first birth, inter-birth intervals, and the age of death). They additionally used this information and tested possible effects of the presence or absence of a post-reproductive mother (grandmother) on the reproductive success of all her children (survival probability of grandchildren), which was embodied by the number of grandchildren reaching minimum the age of 15 years. The results show that the length

of a women's post-reproductive life span as well as the presence of a grandmother have a significant positive effect on the number of grandchildren. Both, sons and daughters, raised more children to adulthood (age of 15 years) when a grandmother was present compared to those families, where a grandmother was absent or died earlier. The presence of a grandmother seems to affect the survival of her grandchildren positively and thus a prolonged post-reproductive life span enhances a women's reproductive success (direct and indirect fitness). Further support is derived from studies that focused on family structures of some traditional societies like the Hadza (ethnic group in Tanzania), the !Kung (ethnic groups in Namibia, Botswana, and Angola), and the Ifaluk (Polynesian ethnic group). In these traditional societies, daughters of post-reproductive women (grandmothers), who provide material goods and other services like helping in child care, raise healthier children compared to those women without such assistance (e.g., Hawkes et al. 1989). The period of time grandmothers can spend helping additionally increases significantly with the age beyond menopause, and grandchildren of older grandmothers show a higher weight and a better health status compared to those with younger (or absent) grandmothers. These findings support the theory that grandmothers contribute to their own (inclusive) fitness by assisting their daughters and sons in raising their own children successfully (Fig. 2).

The By-Product Hypothesis: A Physiological Trade-Off Between Early Fecundity and Longevity

As mentioned before, to understand the evolutionary origin and significance of human menopause has engaged anthropologists and evolutionary biologists for decades. From a Darwinian perspective, natural selection would favor females who become infertile many years before death if offspring requires exceptional duration and intensity of parental care, as is the case with humans. Thus, menopause is an adaptive consequence of natural selection and a solution to the trade-off between investigating in additional offspring or in already existing offspring and their children (grandmother hypothesis). But the grandmother hypothesis seems to be inconsistent with some aspects of

Menopause, Fig. 2 Grandmother providing assistance

the theory about the evolution of aging which leads researchers to the assumption that menopause is rather an artifact of a relatively recent increase in human life span.

This, nonadaptive (nonfunctional) approach for the origin of menopause based on the assumption that menopause has never been directly selected and is not a direct consequence of biological selection for reproductive cessations (e.g., Gosden and Faddy 1998). A better development of health care systems, for example, as well as environmental protection of the contemporary world, improved nutrition, and hygiene, permits women to live beyond the supply of primary oocytes, and thus experience menopause. Adaptations that reduce extrinsic mortality can be generally associated with increased longevity. This idea is supported to some extent by archaeological data on estimated age distributions of skeletal remains and from studies showing that mean life expectancy at birth was close to 40 years in pre-industrial and hunter-gatherer societies. In this context, menopause is seen as a consequence of the increasing life span of humans caused by the industrialization. Thus, as a consequence of the

modernization and the medical progress, menopause seems to be a purely human phenomenon because they are able to live longer after the life period of reproductive ability. But why have these better conditions not affected the reproductive functions (reproductive senescence) in a similar way? According to the life-history theory, increased longevity should come at the cost of reduced fertility. In this view, menopause may represent a trade-off between reproduction later in life, when fertility is naturally lower and birth defects are higher, in favor of some other characteristic that enhances survival and reproduction at an earlier age (e.g., Weiss 1981). Consequently, menopause is considered as a product of antagonistic pleiotropy, favoring early fertility at the cost of late fertility. The antagonistic pleiotropy hypothesis was primarily proposed as an evolutionary explanation for senescence in general. Antagonistic pleiotropy is the phenomenon where one gene controls for more than one phenotypic characteristic in an organism where at least one of these characteristics is beneficial to the organism's fitness and one is detrimental to the organism's fitness. It has been suggested that a gene caused both, increased reproduction in early life and aging in later life, than senescence would be adaptive in evolution.

The Mother Hypothesis

The fact that human females show a gradual decrease in survival and fecundity rates with advancing age (senescence) leads to the assumption that there is probably a close relationship between reproductive fitness and rates of aging and diseases associated with aging. In this context, Williams (1957) developed a further adaptive theory, the "mother hypothesis," to explain the origin of menopause. He proposed that when offspring fitness depends on maternal care and when the risk of maternal and offspring mortality increases with age, then it is more advantageous to stop reproduction to maximize the investment in already born offspring than to continue reproduction with a higher risk of death. The mother hypothesis is supported by the extreme child dependency on adult care of human infants and

the increasing risk of maternal mortality with increasing age. Compared to offspring's of chimpanzees or gorillas, the human infant is proportionally to the mother's weight (on a relative scale) comparatively enormous, which raises in humans the risk of death during childbirth (maternal mortality). Relatively, compared to other species human infants are moreover unusually early born (premature with respect to completion of brain growth and development) and remain highly dependent for extended periods. Infant mortality is high and the onset of puberty occurs late in life. Additionally, child bearing is dangerous and parental care is exhausting and longsome and infant's survival is unlikely if their mother died during childbirth or soon after. This is supported by studies that showed that maternal care significantly influences the change of child survival. The death of a mother, not only soon after birth but also during late childhood and also to prior child's, compromises her child's survival. It is additionally well known that the risk of maternal mortality increases rapidly after the age of 35 years, regardless whether access to modern medicine is available or not. It is also highly supported that the likelihood and frequency of chromosomal abnormalities in new-born children also increase with increasing maternal age.

Regarding the mother hypothesis, menopause occurs because reproductive cessation allows mothers to increase their fitness by investigating on the one hand in survival of immature children and on the other hand in the fertility of their mature children. Thus, older mothers might profit more (genetically) from investing resources in their already existing children than in giving birth to new ones, because with increasing age the risk of stillbirth, birth defects, and the mothers own death during childbirth rise and because of the fact that children need their mothers love and care to survive. Maternal care is therefore a major determinant of offspring survival. So it is more advantageous for a woman to stop reproduction early in life span. In summary, her already living children have a lower risk of dying during their childhood and as a consequence they have a better chance of reaching childbearing age.

Whether a product of natural selection or a side effect, it seems obvious that menopause is strongly linked to aging, which is usually defined as the progressive loss of body function attended by decreasing fertility and increasing natural mortality with advancing age due to complex cellular and molecular changes. There is a general agreement that the evolution of aging is linked to the fact that under natural conditions the organisms' risk to die induced by extrinsic hazards (such as infection, predation, starvation, or cold) increase with increasing age. Furthermore, these extrinsic hazards mainly affect younger individuals and consequently, as a result, most individuals simply do not live long enough to grow old. But reproductive aging in human females takes place long before other body functions senesce which presents an evolutionary dilemma. In order to understand the selective importance of reproductive aging and thus menopause, it is necessary to review some basic facts about the biological system and mechanisms that regulate normal reproductive cycles in adult females. Senescence is described as a decrease in survival and fecundity rates with advancing age. It has been predicted that senescence evolved as a side effect of life-history optimization and longevity has been traded for early high fecundity (Williams 1957). Hence, senescence is supposed to be caused by pleiotropic effects of genes that enhance reproduction at younger ages but suppress also survival later in life.

Menopause is a secondary consequence of the female mammalian reproductive system, which has a physiological limit of about 50 years. From that point on, the egg supply is limited and healthy eggs cannot be maintained with increasing age. The depletion of follicular reserve and the subsequent loss of fertility provide one explanation for how menopause occurs. Female mammals acquire 100% of their primordial follicles prenatal, around the time of birth. Most of this – approximately one million – primary oocytes degenerate before onset of reproductive ability (age of menarche, onset of puberty), so that in case of human females only about 400 primary oocytes are available for reproduction. During the reproductive life span

(adolescence and adulthood) the remaining primary oocytes complete their maturation and are released in series during menstrual cycles. As a result, the female ovarian follicular reserve declines during aging. However, during the reproductive life span the majority of follicles are lost in atretic processes than through to monthly ovulation. At about the age of 50 years, all of the oocytes are depleted and a female that lives according to this age of depletion experiences menopause.

In contrast to what is proposed in the mentioned grandmother or mother hypotheses, menopause is not, itself, adaptive but rather it is the final outcome of a decades-long progress of follicular depletion, which is in turn essential for the maintenance of regular ovarian cycles at younger reproductive ages. Therefore, since follicular depletion in human females causes both, high fecundity in early life (regular menstrual cycles) and loss of fecundity later in life (menopause), it can be selected if the early benefits outweigh the late costs. It is also possible that the physiological mechanisms of the follicular-depletion system and not menopause by itself have influenced the evolution of a prolonged post-reproductive life span in human females. Considering human's evolutionary history, it is also possible that our ancestors rarely survived beyond the age around 50 years, and selection simply produced as many oocytes as would be required, which in turn supports the artifact theory.

The Absent Father Hypothesis

All the previous mentioned hypotheses to explain menopause mainly focused on fitness costs and benefits of women (one-sex models), but it is also thinkable that processes where males are involved and influence menopause (two-sex models). The absent father hypothesis in contrast propose that reduced paternal investment combined with increasing maternal age could be an additional incentive for the evolution of menopause (Kuhle 2007) and represents not an alternative approach to the grandmother or mother hypothesis but is rather an extension of these approaches. The model includes the cross-cultural male mate

preference for female physical characteristics that signal youth and fertility, which is proposed to have evolved because men's reproductive success depends on their ability to gain sexual access to reproductively valuable women. Thus, men show the preference to mate with women displaying those characteristics that can be associated with reproductive ability like youth. Younger women have a higher reproductive value (number of children a woman of a given age can have in the future) compared to older women as younger women have more follicles available for fertilization, have higher fertility, and have lower risks of chromosomal abnormalities. Scientists propose that the evolved male preference for female youth could have prompted our ancestral men to pursue younger women either in place of or in addition to their mates until their mates achieved the age of infertility, to increase their own reproductive success. The evidence for this assumption is that older men prefer women that are increasingly younger than them supports this assumption. Additionally, men wishing to set themselves apart from their middle-aged mates by mating with younger women in addition to or in place of them would probably have reallocated their resources and protection to the younger women which leads to the consequence that the middle-aged women suffered a reduction of paternal investment. There is also evidence that supports the assumption that fathers, who leave their family, spend less parental investment than those who stay in the family. Without the prolonged investment of the fathers, similar to maternal investment, the risk of infant mortality is comparable higher before they reach the reproductive age. Paternal investment seems also to be essential for offspring's survival and because of this a reduction in paternal investment (absent of father) in combination with an increasing maternal age may provide further fitness benefits for the evolution of menopause. Menopause evolved due to the fact that the female abilities to reproduce are terminated and increased women's ability to care for extant offspring's by decreasing the likelihood of having to care for newborns and infants who may not survive until age of reproduction due to decreasing investment of both parents.

Conclusion

In very general terms, according to evolutionary theory, the goal of any organism is to pass on its genes and therefore, the phenomenon of human female's menopause confuses evolutionary theorists and is a highly controversial topic which is still active in research. Menopause refers to the relatively abrupt cessation of the female reproductive ability with about 50 years, when the impact of senescence on most other body functions is still small. Such a decline in age-specific fertility as a function of overall senescence is not uncommon among other species, but in contrast to most other species, human females are unique in experiencing a total cessation of reproductive capacity long before the end of their life. Reproductive aging is based on age-related changes in ovarian function and reduced oocyte quality which lead to menstrual cycle irregularities and changes in monthly fecundity and end ultimately in the total loss of reproductive ability. Whereas neuroendocrine changes that go along with follicular depletion seem to be the proximate causes of menopause; the ultimate causes are still unclear and possible explanations are mixed. To understand and explain the origin and significance of human female menopause has challenged not only evolutionary biologists and anthropologists but also medical scientists for quite a long time. They all investigate possible answers to the questions of why the reproductive ability of human females ends long before other body functions senesce and they thus experience menopause. Trying to find an answer to this question reveals that there are several causes possible and that apparently none of the possible causes can explain the origin of menopause by its own.

The summarized main hypotheses to the origin of menopause are that a prolonged post-reproductive life span could provide grandmothers as well as mothers the possibility to enhance their inclusive fitness by assisting their own children to reproduce successfully instead of raise further own children, or that early infertility could protect mothers from rising risks of age-specific maternal mortality and thereby protect also their highly dependent younger children from death in case the

mother dies. I guess that all theories reviewed here are to some degree possible and played a role in the evolution of menopause. Due to the fact that there is some evidence for each theory and also against, it may be possible that more than one of these models could account for the evolution of menopause. Thus, menopause is probably the result of a dynamic interaction of all the advantages and disadvantages that arise within these theories and that led to a prolonged post-reproductive life span which makes in this manner human females unique.

Menopause Affords Grandparental Investment

Austin Jeffery

Menopause as a Kin Selection Adaptation
Sessation of Ovulation for Offspring Investment

Definition

It has been proposed (Austad 1994) that menopause is an adaptation that allows older females to provide enhanced care to their kin group. This is one interpretation of the grandmother hypothesis.

Introduction

The grandmother hypothesis proposes that the function of postmenopausal (i.e., post-reproductive) life in females is to provide enhanced care to kin. One interpretation of this hypothesis is that menopause represents an adaptation to make reproduction impossible. Specifically, menopause evolved as an adaptation to reduce the risk of late-life pregnancy in women who have (i) accumulated more germ-line mutations, (ii) become less likely to survive childbirth or produce a live child, and (iii) carry genes that could better benefit from investing in large numbers of kin rather than producing offspring. In this

account, the cessation of ovulation occurs in mid-life to facilitate a new familial role as a grandparent. It may seem counterintuitive for an adaptation to cause infertility, but if a grandmother or aunt can provide enough investment into their developing kin, they can substantially increase the likelihood that those kin survive and reproduce themselves. The theory of kin selection outlines how one can benefit their own genetic replication by improving the odds that their close kin survive and reproduce, because close kin will tend to also carry that same genetic information. A set of genes that promote grandmothering investment will proliferate more effectively if it can identify and support kin members who are more likely to carry those genes.

Evidence

This interpretation of the grandmother hypothesis makes several testable predictions. First, it must be possible to offset the cost of infertility by promoting the survival and reproductive success of kin. Studies of this topic have given mixed results. There is limited evidence that kin investment improves outcomes for children in industrialized societies (Coall and Hertwig 2010; Hawkes 2004) and stronger evidence that child life-expectancy in non-industrialized societies is improved by the presence of a maternal grandmother (Strassmann and Garrard 2011). However, when modeled mathematically, kin assistance provided by older females does not produce positive selection on genes for postmenopausal longevity (Kachel and Jean-Jacques Hublin 2010). In other words, grandmothers do provide measurable improvements to kin survival, but it is not clear whether this is enough to offset the costs of menopause.

Second, if menopause is an adaptation, one would expect to find evidence of special design or clues that the process of menopause is a controlled feature of female physiology rather than a consequence of physiological necessity. Oocytes are immature egg cells (ova) that are maintained in follicle tissue across the life-span. Human females are born with about one million oocytes, but these cells rapidly degrade such that 400,000 remain at

puberty and none remain around age 50 (a total of about 400 are released through ovulation in a lifetime). Oocyte depletion is regarded as a biological constraint on the female reproductive life-span. The process of menopause includes changes in hormone concentrations, psychological processes, and physiological maintenance but does not show the relaxed oocyte maintenance that would be expected if menopause itself were an adaptation.

Third, if menopause is an adaptation, one would not expect to observe the same process in nonhumans as they approach death. This is less an unsupported prediction than a logical challenge to the adaptation interpretation of menopause. Chimpanzees and gorillas observed in captivity show preliminary signs of menopause, and especially long lived chimps appear to show full ovulatory cessation at roughly the same age as female humans (40–50 years; Thompson et al. 2007). Menopause appears to be a conserved primate feature; humans are unique only in continuing to live after menopause has occurred.

Conclusion

The idea that menopause, or the cessation of ovulation, is an adaptation for providing better care to kin has fallen out of favor among most evolutionary theorists. There exists an alternative rationale for the grandmother hypothesis whereby human females have experienced selection for longevity rather than for the cessation of ovulation. Longevity could be selected on the basis that it promotes grandparental investment, and the fact that females will live longer than their oocytes is a by-product of selection for longevity. This rationale is described in extended postmenopausal life-span.

Menstrual Cycle

Anastasia Makhanova
Florida State University, Tallahassee, FL, USA

Synonyms

[Ovulatory cycle](#)

Definition

In women, the cycle of regular natural change within the reproductive system that includes ovulation and menstruation and makes pregnancy possible.

Introduction

From puberty to menopause, women who are not pregnant experience a menstrual cycle – a regular set of fluctuations in their reproductive hormones. This entry will focus on several key aspects of the menstrual cycle: (a) a description of the normal menstrual cycle, (b) potential disruptions (e.g., pregnancy, birth control, and amenorrhea) of the normal menstrual cycle, and (c) numerous psychological and behavioral changes associated with the menstrual cycle.

Description of the Normal Menstrual Cycle

A normal menstrual cycle lasts approximately 28 days on average, although some research shows that a normal cycle can range from 24 to 35 days (Stern and McClintock 1998). The menstrual cycle consists of three phases: follicular, ovulatory, and luteal. The menstrual cycle begins with the onset of menstruation, the shedding of the uterine lining from the previous menstrual cycle (which occurs during the follicular phase of the current cycle). During the follicular phase, the follicle-stimulating hormone (FSH) facilitates the maturation of a dominant follicle (sometimes two) that is capable of releasing an egg during ovulation. Estrogen rises, preparing the cervix and uterus for fertilization. At the end of the follicular phase, estrogen peaks and is then followed by a surge of the luteinizing hormone (LH).

The ovulatory phase is the fertile phase of a woman's menstrual cycle. Ovulation occurs approximately 30 h after a detectible LH surge (Bullivant et al. 2004). During this phase, a mature egg is released from an ovary and travels down one of the fallopian tubes where it may be fertilized by a sperm. If the egg is not fertilized, it disintegrates in the fallopian tube. If the egg is fertilized, it begins to develop as it moves down the fallopian tube to implant in the endometrium, or the wall of the uterus. Women are able to conceive on the day of ovulation and up to 5 days prior (Wilcox et al. 1995). In research, the term ovulation (or ovulatory phase) often refers

not only to the day the egg is released but to the whole fertile window (and follicular phase refers to all days of that cycle before the fertile window).

After ovulation, the body begins preparing for possible pregnancy. The luteal phase, which lasts approximately 14 days (Baird et al. 1995), is associated with the creation of the corpus luteum (a temporary structure on the ovary that forms from the dominant follicle after it has released the egg) that begins to release progesterone and, to a lesser extent, estrogen (Gilbert 2000). If the egg is not fertilized in the ovulatory phase, progesterone levels continue to rise until the corpus luteum cannot maintain itself, at which point progesterone plummets and a new menstrual cycle begins with the onset of menstruation (Gilbert 2000). If the egg is fertilized in the ovulatory phase, the embryo produces a hormone (human chorionic gonadotropin, hCG) that aids in maintaining the corpus luteum for approximately 10 weeks until the placenta takes over progesterone production (Yoshimi et al. 1969).

To summarize, the follicular phase occurs at the onset of menstruation and is characterized by a rise of estrogen as the woman's body prepares for possible egg fertilization. The ovulatory phase is the fertile phase of women's menstrual cycle and is conceptualized as the 5 days leading up to and the day of ovulation. The luteal phase is characterized by a substantial rise in progesterone and a smaller rise in estrogen as women's bodies prepare for possible pregnancy. If no pregnancy is detected, the menstrual cycle starts over.

Estimating the Phases

The menstrual cycle phases can be determined in three ways (reviewed in Gangestad et al. 2016). One method involves counting forward from the onset of menstruation. The only information needed for this method is the previous menstruation start date. In this method, the follicular phase includes the first 8 days of the menstrual cycle, the ovulatory phase includes days 9–14, and the luteal phase includes day 15 until the onset of the next menstruation. The forward-counting method is the least accurate but most easily conducted method of determining menstrual cycle phase.

A second method of assessing menstrual cycle phase involves counting backward from the onset of the next estimated menstruation. Two pieces of information are needed for this method – the previous menstruation start date and the average menstrual cycle length (which is used to determine the estimated start date of the next menstruation). In this method, the luteal phase includes the 14 days preceding estimated menstruation, the ovulatory phase includes the 5 days before the luteal phase (i.e., days 15 through 20 when reverse counting), and the follicular phase includes the days between the previous onset of menstruation and the ovulatory phase. The backward-counting method is considered more accurate than the forward-counting method for determining the ovulatory phase because women's luteal-phase length varies considerably less than their follicular-phase length (Baird et al. 1995). This method, however, requires following up with women to confirm the accuracy of their next estimated menstruation, which may complicate the research methodology and may result in fewer qualified research participants due to attrition (a lack of responses to the follow-up from the women who had participated).

The third and most accurate method of assessing menstrual cycle phase involves first estimating women's ovulatory phase (using either the forward- or backward-counting method) and then confirming the LH surge using a urine-detection test. In this method, women typically use an over-the-counter LH test every morning, starting on the tenth morning of their menstrual cycle. Because ovulation occurs 30 h after the detectable LH surge (Bullivant et al. 2004) and the fertile window is comprised of the day of ovulation and up to 5 days prior (Baird et al. 1995), researchers can accurately estimate the fertile window after confirming an LH surge. The days of that menstrual cycle prior to the estimated fertile window are considered the follicular phase, and the days of that menstrual cycle following the estimated fertile window are considered the luteal phase. Further, between-subjects designs require exceptionally large samples in order to detect effects; utilizing a within-subjects methodology is encouraged (Gangestad et al. 2016). Additionally, it is

recommended to recruit a sample with the knowledge that approximately half of participants will not have a detectable LH surge.

Disruptions of Regularity

Although a normal menstrual cycle occurs every 24–35 days, various factors can interrupt or change these normal hormonal fluctuations. Prior research has suggested at least three factors that suppress ovulation: (a) pregnancy and the postpartum period, (b) hormonal contraceptives, and (c) amenorrhea.

Pregnancy and the Postpartum Period

As previously described, if an egg is fertilized and an embryo successfully implants in the uterus, that embryo produces hCG to help maintain the corpus luteum and prevents menstruation from occurring. Throughout pregnancy, progesterone levels rise – produced first by the corpus luteum for 10 weeks and then by the placenta (Yoshimi et al. 1969). This increase in progesterone suppresses the menstrual cycle for the (typical) 40 weeks of gestation. The postpartum period follows childbirth and lasts an additional 6 weeks during which hormones begin returning to prepregnancy levels.

The return of hormones to prepregnancy levels, however, may be interrupted by lactation and consequent breastfeeding for several months (Kippley and Kippley 1972). Indeed, prolactin surges following infant suckling and the disruption of LH production associated with breastfeeding prevent ovulation from occurring. Once suckling declines and the infant is weaned, however, the preovulatory LH surge reoccurs. Notably, the amount of time that women take to return to normal hormonal fluctuations after lactation can vary.

Hormonal Contraceptives

Modern women often use hormonal contraception as a method of birth control to avoid conception during sexual activity. Hormonal contraceptives affect the endocrine system and disrupt the normal menstrual cycle. For example, progestogen-only hormonal contraceptives disrupt ovulation

through a negative-feedback process that disrupts FSH and LH. Likewise, combined hormonal contraceptives that include both progestogen and estrogen more effectively disrupt ovulation through the negative feedback from both hormones. Because ovulation is disrupted, women using hormonal contraceptives do not experience the psychological changes (reviewed in the next section) associated with the menstrual cycle even though they may still experience menstruation (facilitated by a drop in progesterone if women using oral contraceptives take placebo pills). For example, after starting to take hormonal contraceptives, women demonstrated lowered preferences for masculine features when compared to their own preferences when they were normally cycling (Little et al. 2013). Furthermore, some research suggests that there are long-term psychological effects of the disruption of the menstrual cycle for some individuals (see Russell et al. 2014). More details about hormonal contraceptives and their effects can be found in some of the cross-referenced encyclopedia references.

Amenorrhea

Some external circumstances may cause amenorrhea, or the cessation of a menstrual cycle in women of reproductive age that is not due to menopause. One common cause of amenorrhea is low body weight and can be achieved both through dieting and exercising. Thus, intense exercise and weight loss have the potential to disrupt the normal menstrual cycle. A second common cause of amenorrhea is stress. These disruptions in the normal hormone fluctuations within the menstrual cycle would also disrupt the psychological and behavioral shifts associated with those fluctuations.

Psychological Fluctuations Associated with the Menstrual Cycle

The hormone fluctuations associated with the menstrual cycle affect women's behavior and sometimes the behavior of men toward them (Makhanova and Miller 2013). For instance,

women may be especially motivated by mating during the ovulatory phase (when they are most fertile) but motivated by affiliation and self-protection during the luteal phase (when their bodies are preparing for possible pregnancy). In the next two sections, research on both of these motivations is reviewed.

Motivations Associated with the Ovulatory Phase

From an evolutionary standpoint, ancestral women who engaged in more sexual activity during their fertile window would have had greater reproductive success than women who failed to take advantage of the narrow opportunity for conception. Thus, as a result of these evolutionary pressures, it may have been adaptive for women to shift their behavior and cognition toward a mating focus during the ovulatory phase. Indeed, women experience increased sexual desire (Bullivant et al. 2004) and a shift in mating strategies (for a review, see Gildersleeve et al. 2014) a few days prior to and during ovulation. For instance, near peak ovulation, women are more likely to approach desirable partners and distance themselves from undesirable partners (for a review, see Haselton and Gildersleeve 2016). Further, consistent with the notion that such behaviors are perceived as highly attractive, women are more likely to wear more revealing clothing and red/pink colors (Beall and Tracy 2013; Haselton et al. 2007; Prokop and Hromada 2013). Thus, research supports the hypothesis that the ovulatory phase of the menstrual cycle results in behavioral and cognitive changes associated with mating motivation.

Moreover, a growing literature suggests cues of ovulation affect men's physiology, cognitions, and behaviors (for a review, see Makhanova and Miller 2013). For example, men perceive women's scents to be more attractive during the ovulatory phase compared to a non-ovulatory phase (Miller and Maner 2011). Further, men perceive women's dancing as more attractive during ovulation than during a non-fertile phase (Fink et al. 2012). Indeed, one study found that exotic dancers received more tips when they were ovulating than when they were not (Miller

et al. 2007) suggesting that men's behavior may also be affected by cues to ovulation.

Motivations Associated with the Luteal Phase

As women's bodies prepare for possible pregnancy (notably, whether or not the egg is actually fertilized), women may also undergo psychological preparations for dealing with the pressures from pregnancy. Specifically, pregnancy is associated with several threats. Pregnancy greatly limits women's abilities to locomote, acquire resources, and expend energy to pursue their goals. Thus, women may benefit from allies and social support at a time when these threats are more probable and extra costly (Taylor et al. 2000). Accordingly, the luteal phase of the menstrual cycle may be associated with psychological changes associated with an increased motivation to affiliate and protect oneself.

Indeed, women seem to be especially attuned to their social environment during the luteal phase of their cycle. Although women demonstrate greater levels of affiliation during the luteal phase (Schultheiss et al. 2003), women likely benefit from being selective in their affiliations because of the increased threats during pregnancy. Consistent with this notion, women attend more to social stimuli during the luteal phase of the menstrual cycle compared to the follicular phase of the menstrual cycle (Maner and Miller 2014). This increased social monitoring may aid women in achieving both affiliative and self-protective goals. Research has found support for the hypothesis that luteal phase affects social perception. When judging emotions of disgust and fear on others' faces, women judged these emotions to be more intense when they were in the luteal phase compared to the follicular phase (Conway et al. 2007). Furthermore, women seem to be extra sensitive to and overperceive these emotions during the luteal phase (Derntl et al. 2008; Guapo et al. 2009). That is, women may be more attentive to potential threats in their social environment during the luteal phase. Furthermore, an fMRI study found an interaction between cycle phase and neural stress reactivity; specifically women in the mid-luteal phase were more attuned to social stress and experienced greater hippocampal

activation compared to early-follicular women (Chung et al. 2016). Thus, a growing body of literature supports the hypothesis that menstrual cycle phase influences women's affiliation and self-protection motivation. Women tend to pay more attention to social cues and social threat in the luteal phase, when their bodies undergo physiological processes to prepare for a potential pregnancy (a status when women would become extra vulnerable to threats).

Conclusion

Women of reproductive age experience regular fluctuations in their reproductive hormones. The cycle lasts approximately 28 days on average and is comprised of three phases: the follicular phase, the ovulatory phase, and the luteal phase. The follicular phase prepares the ovaries and uterus for ovulation (and includes menstruation). The ovulatory phase is when women are fertile and able to conceive. The luteal phase prepares the uterus for pregnancy. In addition to these physiological changes, research has demonstrated that the normal menstrual cycle is also related to psychological preparations associated with the evolutionary pressures related to the cycle phases. During their ovulatory phases, women report greater mating motivations that correspond with their increased conception probability. During their luteal phases, women report greater affiliation and threat-avoidance motivations that correspond with the increased physical limitations associated with pregnancy and subsequent need for both vigilance to the social environment and allies.

Some scholars have argued that behavioral shifts associated with women's menstrual cycles are illogical because such behaviors should be conscious decisions that are immune to fickle manipulations. Drawing from an evolutionary standpoint, however, it is illogical not to take into account conception risk and pregnancy when examining human psychology because those states have profound implications for women's reproductive fitness and abilities to survive and to achieve other goals.

Meta-analysis of Sex Differences in Aggression

Nikki Clauss, Ashley Rankin and Jennifer Byrd-Craven

Oklahoma State University, Stillwater, OK, USA

Synonyms

Competition; Female-female competition; Hostility; Indirect aggression; Intrasexual competition; Male-male competition; Physical aggression; Verbal aggression

Definition

Aggression is a response by an individual that delivers something aversive to a target. It can be expressed directly, in the form of physical and verbal aggression, or it can be expressed indirectly, in the form of social isolation and ostracism, known as relational aggression.

Introduction

Among humans, physically aggressive behavior in childhood peaks between 2 and 4 years of age and declines steadily in both sexes until adolescence (see below) (Archer 2009). Despite this decline, sex differences persist throughout childhood and into adulthood. There are a fraction of

individuals who maintain the high level of physical aggression seen early in development, and the majority of them are male. Similarly, there are a small fraction of individuals who demonstrate unusually low levels of physical aggression early in development and throughout childhood, and nearly all of those individuals are female. While verbal and relational aggression are more equally distributed between males and females, relational aggression is more common in girls and women, and they are more sensitive to it.

Cross-culturally and to varying extent, men are more likely to use physical aggression than women (Archer 2009). However, where the rate of criminal violence is high, the female rate is also high. The peak of violent behavior in both sexes corresponds to the attainment of sexual maturity, with the female peak occurring earlier than the male peak. In industrialized societies, aggressive behavior is associated with poverty, poor education performance, and dysfunctional parenting for both sexes, which suggests a common underlying mechanism responsive to the same ecological and life history variables. Many have asserted that this may be due to inadequate opportunities to compete for socially valuable resources in other ways, as physical aggression is often redirected in more affluent contexts toward organized coalitions with socially sanctioned aggression (i.e., organized sports) or other forms of competition.

Parental Investment Theory

Parental investment theory provides a useful framework in which to understand sex differences in aggressive behavior. Parents invest resources toward their offspring at the expense of future offspring (Trivers 1972). In most species, investment in gestation and postpartum care creates differences in the potential rate of reproduction and results in the higher investing sex being the limiting resource for the lower investing sex. For most mammals, females are the higher investing sex, and the result in the costs of physical aggression on reproductive fitness is higher (Sear and Mace 2008). In most mammals, the extent of male investment is copulation, with no or little

offspring care or provisioning. This polygynous strategy fuels intrasexual competition for access to mates and the resources they need to successfully raise offspring, and this competition is often physical. Although this strategy can be costly (i.e., potential for death), the benefits of this approach (gene representation in future generations) appear to outweigh the potential costs for males. In many contexts, physical aggression results in control of resources and status, increasing potential for reproductive success.

Physical Aggression

Practice with physical aggression occurs during development, as is the case with many other species. For humans, rough-and-tumble play provides the preparation needed to develop social-competitive skills, at least for most of human history. Though rough-and-tumble play is not exclusive to boys, it occurs with much higher frequency and much more vigor than with girls. This sex difference is robust, as it has been found across all modern and traditional societies in which it has been studied and first emerges around 3 years of age (Eibl-Eibesfeldt 1989; Maccoby 1998). It is consistent with practices for establishing within group dominance relationships as well as coordinating attacks for coalitional maneuvers. The extent and form of rough-and-tumble play can vary across traditional and modern contexts and is dependent on the relative frequency of physical aggression among adults in the culture, including intergroup conflict (Charlesworth and Dzur 1987; Whiting and Edwards 1988). The sex difference in rough-and-tumble play peaks between ages 8 and 10, and as boys move toward adolescence, it often intensifies to outright physical aggression. Importantly, the establishment of a dominance hierarchy is often associated with reductions in aggressive behaviors in boys (Pelligrini and Bartini 2001).

Later in development, physical aggression is predicted by access to resources (including mates), status, and the potential for aggression to result in gains in both. The magnitude in the sex

difference, favoring males, for physical aggression increases as males move through adolescence and into early adulthood. Whether using self-reports, observation, or homicide records, there are significant and substantial sex differences in physical aggression, even in industrial societies, where there are constraints on men's ability to utilize physical aggression (Archer 2009). If one primary function of physical aggression is to gain access to mates and associated resources, then it would be expected to be most intense during years in which reproductive competition is highest. Historical and cross-cultural crime records show that men's involvement in crimes involving physical aggression and in male-on-male homicides is highest between ages 18 and 30 (Daly and Wilson 1990, 2001). Self-reported physical aggression is also highest during this developmental period (Archer 2004).

Relational Aggression

Alternatively, in both traditional and industrial societies, girls and women pursue a less physically risky strategy of competing for resources: subtly organizing their social world in ways that benefit them and their children. Behavior related to this strategy is referred to as relational aggression and involves the use of gossip, rumors, and lies to socially isolate and disrupt the social and sexual reputation of potential competitors (Grotper and Crick 1996). This can be effective in that disruption in the social support systems of women can negatively influence their health and that of their children (Taylor et al. 2000). While both sexes engage in relational aggression, just as in physical aggression, it is the female strategy of choice. There is evidence that women are more sensitive to relational aggression and react more strongly to these social tactics (Benenson et al. 2013). Relational aggression begins as early as preschool age but typically peaks in adolescence, when intrasexual competition is often highest.

Females are tasked with gestation, lactation, and, often, significant postpartum care until offspring reach maturity. Therefore, a mother must provide adequate nutrition and protection from

ecological dangers during the time her offspring are dependent. Females often do not compete for resources physically, as do males. One possible reason for this is that the potential cost of physical aggression is death (Cross and Campbell 2011). Because her offspring's survival is most heavily dependent on the continuation of the mother's investment, the potential cost of physical aggression is often too high a price to pay. This is not to say that women are not competitive and aggressive with one another. This competition is, on average, more indirect than with boys and men, and the focus differs. Unlike many other mammals, paternal investment is common in humans, though the extent is variable across contexts. Paternal investment is linked to the offspring survival rate and social status and is thus a valuable reproductive resource for women (Geary 2010). Further, women would be expected to compete over paternal investment, particularly given that paternal investment is more variable and context dependent than maternal investment (Geary 2010). This creates circumstances in which women must compete for quality paternal investment, while at the same time reducing risks to herself and her dependent children.

The preference for less-risky aggression tactics has also been observed in nonhuman females. This includes behaviors such as establishing dominance hierarchies, territorial aggression (i.e., defending a home range), and coordinated aggression and constraining the reproduction of others (Stockley and Bro-Jørgensen 2011). Chimpanzees have been shown to use a number of these tactics including aggression toward new residents and interfering with their competitors' mating, female-led infanticide, and dominance hierarchies, typically organized around access to food resources (Pusey and Schroepfer-Walker 2013). Female dominance hierarchies have also been observed in other mammals such as vervet monkeys, chacma baboons, bison cows, reindeer, and house mice (Stockley and Bro-Jørgensen 2011).

Emotion

Emotion is a potential psychological mediator of sex differences in aggressive behavior (Cross and

Campbell 2011). The meaning of emotions depends on the outcomes they have been associated with over the course of evolutionary time. The emotions of fear and anger inform approach-avoidance distinctions in behavior that underlie aggression. Anger is positively related to approach motivation and negatively related to avoidance motivation. It increases sympathetic nervous system activity in preparation for exertion and combat. However, there is no evidence for sex differences in the experience of anger.

Unlike anger, fear is negatively associated with approach motivation. The fear system activates responses that maximize survival (i.e., avoidance motivation) in response to perceived danger. There are also marked sex differences in the experience of fear. The hypothalamic-pituitary-adrenal (HPA) axis response to stress is inhibited by androgens and enhanced by estrogens. Further, gonadal hormones lead to the fear system developing differently in males compared to females. Behaviorally, girls begin expressing fear earlier than boys and are more likely to develop on a high fearfulness trajectory. In adulthood, women experience fear more frequently and intensely than men. This lower threshold for experiencing fear leads women to appraise the same objective situation as more dangerous than men do. This evaluation difference explains significant variation in sex differences in aggression (Campbell 2006).

Partner Aggression

Partner aggression is a domain in which aggression occurs at apparent sex-equal rates, though women are more likely to be seriously injured or killed as a consequence of partner aggression than men are (Daly and Wilson 1988; Archer 2000). This suggests that male aggression (typically higher than that of females) is being constrained and female aggression (typically lower than that of males) is being disinhibited (Cross and Campbell 2011). Culture has been suggested as a potential explanation for this phenomenon. For example, in cultures where women are more socially and legally equal to men, women also engage in more partner-directed aggression.

These cultures also typically have strict sanctions against domestic violence, and men are taught from boyhood that it is inappropriate to behave aggressively toward women. However, it is important to note that even in cultures where women are less legally and socially equal to their male counterparts, rates of partner violence committed by women are not trivial (Archer 2006).

Role of Hormones

Oxytocin, a nonapeptide hormone and neuromodulator, has also been suggested to potentially play a role in the sex differences observed in partner aggression. There is evidence that oxytocin is involved in a wide range of cooperative and reproductively relevant behaviors (Pederson 2004; Campbell 2010). Further, oxytocin receptors are upregulated by estrogen, possibly making it a particularly important player in female behavior (Lim and Young 2006). Therefore, women in romantic relationships are producing oxytocin consistently in response to reproductive cues. Oxytocin is associated with a reduction in amygdala activity in response to fear-provoking stimuli and reduces connectivity between the amygdala and regions of the brain associated with sympathetic nervous system responses to threat, thereby reducing the experience of fear. Therefore, oxytocin may be one mechanism by which women are overall less physically aggressive, but similarly physically aggressive within their romantic relationships (Campbell 2010).

In addition to cultural explanations and the possible mediating role of oxytocin, there are sex differences in the motivation for aggressive behavior which may provide some explanation for the sex-equal rates of aggression within romantic relationships. Males and females use aggression for mate guarding. Males use mate guarding as a technique to maximize paternity certainty, while females utilize mate guarding to maximize male investment. In addition to mate guarding, females are also more likely to use aggression toward their partner due to displaced anger (i.e., people aggressing to a target other than the one that provoked them; Archer 2004).

Conclusion

Sex differences in parental investment and associated social selection pressures have resulted in differences, on average, between the sexes in aggressive tactics, particularly those related to intrasexual competition. There are established differences in the extent to which girls and boys self-initiate and thus practice and refine and behavioral competencies that facilitate these forms of competition in adulthood. Cultural demands then direct these sex differences in divergent or convergent directions, depending on the level and nature of competition and access to resources in the current context.

Definition

Metacognition is the awareness and understanding of one's own thought processes. It involves monitoring processes that ascertain current states of knowledge and control processes that seek information when needed and generate confidence measures.

Introduction

Metacognition refers to the observation that one can be cognizant of one's own cognition and may therefore be in a position to regulate it. Theoretically, metacognition includes two key aspects: (1) The executive monitoring of cognitive states which is an endogenous process that is sensitive to the state of uncertainty in a given judgment or decision context and (2) The information provided by the metacognitive monitoring can alter or control other cognitive processes to

affect decision-making. Metacognition has been extensively studied in humans and is an important concept that captures some of the essence of what it means to be a “conscious agent.”

Comparative research in metacognition illuminates the shared cognitive capabilities of human and nonhuman animals that might be accessible to a metacognitive system while also better defining the uniqueness of human metacognitive capacities. Human metacognitive research often involves verbal reports about one’s own knowledge. However, nonhuman animal (“animal” hereafter) metacognition has been investigated extensively using experimental tasks that infer metacognition by assessing how animals behave when faced with stimuli and choices that might evoke varying degrees of confidence or uncertainty (Smith 2009). Animal metacognitive research could provide evidence of rudimentary forms of self-awareness, or theory of mind, in other species that do not have the benefit of language to mediate its expression. This research area also potentially outlines the earliest emergence of self-reflective minds in animals, including those hominid species that led to modern *Homo sapiens*. As such, this research area provides key insights into the evolutionary foundations of humans’ advanced forms of metacognitive control and monitoring. The procedures that assess metacognition in animals also could be adapted for testing metacognition in preverbal or nonverbal humans or even in young children who lack some of the key aspects of mind that older humans have.

Approaches to Demonstrating Animal Metacognition

Positive Evidence

A diverse range of experimental procedures have been used to assess metacognition in a variety of species. Smith et al. (1995) trained humans and a dolphin (*Tursiops truncatus*) to discriminate between a high pitch tone (2100 Hz) and lower pitch tones (varying between 1200 and 2099 Hz). Along with making a “High” or “Low”

discrimination response, the dolphin could emit an “Uncertain” response to decline the trial and proceed to a trial ending with a guaranteed reward. The dolphin’s Low or High responses were accurate for perceptually easy trials, and his accuracy was lowest at the perceptual threshold (about 2080 Hz) for distinguishing between a 2100 Hz tone and lower pitch tones. Choice of the uncertainty response and hesitation in responding both peaked near the point that High or Low responses were equiprobable. These data provided some of the earliest experimental evidence that animals may experience uncertainty akin to humans, and this methodological approach became one of the dominant approaches in comparative cognition. Smith et al. (1997) arranged a similar perceptual discrimination task separately for humans and macaques (*Macaca mulatta*) using a computer test system. Subjects had to judge whether a stimulus sample contained either a dense (2950 pixels) or sparse (450–2949 pixels) matrix of randomly placed pixels or they could make an Uncertain response and decline the trial and proceed to a guaranteed win trial. Humans and monkeys generated very similar results where the point of equiprobable judgment was approximately at 2700 pixels and the use of the Uncertain response peaked near that location along the perceptual gradient (Fig. 1). The humans self-reported that they felt unsure how to classify the pixelated stimulus when they utilized the Uncertain response, demonstrating that this task generated a conscious self-report of uncertainty that is common in human metacognition studies.

Shields et al. (1997) followed with an experiment where macaques and humans made same/different judgments between two-pixel density samples. This task was more complex because it required a relativity judgment between two samples rather than an assessment of one sample. Humans and macaques performed similarly on the task and efficiently used the uncertainty response to escape difficult trials (Fig. 2). Subsequent approaches demonstrated that macaques also adaptively and appropriately used this uncertain response when they received only deferred feedback for their responses (Smith et al. 2006)

Metacognition, Fig. 1 (a) Performance by a monkey in a sparse-dense discrimination. The horizontal axis indicates the density of the trial. The dense response was correct for 2,950-pixel trials – these trials are represented by the rightmost data point for each curve. All trials with fewer pixels deserved the sparse response. The *solid line* represents the percentage of trials receiving the uncertainty response at each trial level. The percentages of trials ending with the sparse response (*dashed line*) or dense response (*dotted line*) are also shown. (b) The performance of

humans in the sparse-dense discrimination depicted in the same way. To equate discrimination performance across subjects, the data were normalized to place each subject's discrimination crossover at a pixel density of about 2,700 (Data are redrawn from "The Comparative Psychology of Uncertainty Monitoring and Metacognition," by J. D. Smith, W. E. Shields, and D. A. Washburn, *Behavioral and Brain Sciences*, 26, p. 322. Copyright 2003 by the Cambridge University Press. Reprinted with permission.)

Metacognition, Fig. 2 (a) Performance by two monkeys in a same-different task. The horizontal axis gives the ratio between the densities of the comparison box and the standard box for trials of different disparities. The same response was correct for trials at a proportional box disparity of 1.0. These trials are represented by the rightmost data points. All other trials deserved the different response. The *solid line* represents the percentage of trials receiving the

uncertainty response at each density ratio. The percentages of trials ending with the different response (*dashed line*) or same response (*dotted line*) are also shown. (b) Performance by six humans in the same-different task depicted in the same way (From Shields et al. (1997). Copyright 1997 by the American Psychological Association. Reprinted with permission.)

and when monkeys had to work on a concurrent task while also making these discriminations (Smith et al. 2013).

Metacognition also has been investigated using metamemory paradigms where the ability or inability to remember a stimulus is monitored instead of the inability to detect perceptual

features of stimuli. Hampton (2001) conducted an experiment where macaques worked on a delayed matching-to-sample (DMTS) task where the Uncertain response would allow the monkey to "settle" for a less preferred reward than it could otherwise receive for making a correct matching response (but, also allow the monkey to avoid a

costly timeout for an incorrect response). As the delay interval increased in length, the monkeys were more likely to use the Uncertain option. In probe trials, where no sample stimulus was presented (i.e., there was nothing to remember), the monkeys continued to use the Uncertain option appropriately. In a related approach, Smith et al. (1998) designed a serial position meta-memory task where trials presented a list of pictures (ranging from 2 to 6) followed by the presentation of a sample picture. If the macaques correctly remembered that the sample picture was in the preceding list or correctly remembered that it was not, then they would earn a reward. Alternatively, monkeys could escape the test trial with an Uncertainty response. The longer the list length the more likely the monkeys were to escape it (Fig. 3). Also, if the serial location of the list

picture was difficult to remember (e.g., the second item in the list that does not benefit from primacy or recency effects), there was a lower probability of correctly remembering it and a corresponding higher probability of escaping from those trials. Overall, monkeys have demonstrated an ability to avoid taking memory tests on trials where they seem to have forgotten the correct response, and this further supports the generality of this animal metacognition paradigm's claims that uncertainty monitoring is responsible for the use of the escape response.

Uncertainty responding as a means to seek information has been investigated in more naturalistic environments (ostensibly, uncertainty monitoring did not evolve as a means to solve computerized laboratory tasks). Call and Carpenter (2001) presented orangutans (*Pongo pygmaeus*)

Metacognition, Fig. 3 Performance by a macaque in a metamemory task. (a) The serial position (1–4) of the probe picture in the list of pictures is also given along the X-axis for probes. NT denotes probe pictures that were not there in the memory list of pictures. The percentage of total trials that received the uncertainty response is shown (solid line). The percentage correct (of trials on which the memory test was accepted) is also shown (dashed line).

(b) Percentage error rates by two macaques (black and gray bars) when the difficulty of the memory test was increased by increasing the length of the memory list from 2 to 4 to 6 pictures. (c) Percentage uncertainty responses (URs) by the two macaques when the difficulty of the memory test was increased in the same way (From Smith et al. 1998. Copyright 1998 by the American Psychological Association. Reprinted with permission.)

and chimpanzees (*Pan troglodytes*) with a task where a food reward was hidden in one container within an array. If these apes witnessed the baiting of the cups (i.e., they knew where it was hidden), they would immediately point to the baited location without investigating that location first, but if they did not see where the food was located they would visually inspect the container to seek information they needed to make a correct pointing response. Hampton et al. (2004) reported similar findings with rhesus monkeys. Suda-King (2008) presented orangutans with a task that also involved choosing among cups where only one was baited with food. In this case, the orangs could not inspect the cups. Rather, they had the option also to choose a cup which always held a smaller reward rather than risk choosing an empty location and receiving nothing. Suda-King reported that when the location of the larger reward amount was known (i.e., the orangutans saw the baiting), they chose those locations, but when they could not know, they were more likely to accept the small-reward option. Beran et al. (2013) expanded upon the premise of this task using chimpanzees. The apes were tasked with correctly reporting to a naïve researcher what food item they had seen inside of a box. They reported symbolically using a lexigram keyboard where specific objects were represented by various key symbols. In the “known” condition the food was shown to the apes prior being hidden in another location, and in the “unknown” condition the box’s contents were not shown but the apes could travel to inspect the box’s contents. The apes were more likely to travel to inspect the box when the contents were not previously shown, but they were more likely to name the item without inspecting the box when the item already was known.

Confidence judgments also can be assessed by allowing the subject to “bet” on whether its response to given trial is likely to end in reward. Middlebrooks and Sommer (2011) had macaques work on a signal detection task where a sample stimulus appeared in one of four corners on a screen and then after 16.7, 33.3, 50, or 66.7 ms (randomized by trial) all four corners presented identical stimuli. The monkey had to respond to the corner where the first sample appeared.

Following a response, a two-option choice was presented where selecting one option expressed confidence in the prior signal detection response, while the other option expressed uncertainty. Reward amount was calibrated based upon whether the monkey was correct/incorrect and whether the monkey made a high confidence or low confidence bet. A high confidence-correct outcome resulted in five drops of juice, while a high confidence-incorrect outcome resulted in a 10 s timeout. A low confidence-correct outcome resulted in three drops of juice, while a low confidence-incorrect outcome resulted in two drops of juice. Response accuracy increased as the sample-choice delay was increased, and the monkeys’ ratings of confidence in their response increased concomitantly. Thus, the monkeys’ betting behavior tracked their accuracy.

Ambiguous Evidence

In addition to humans, dolphins, and macaques, research has been conducted with pigeons, rats, bantams, and capuchin monkeys (*Cebus apella*) to assess potential metacognitive capacities. Many of these approaches have produced more ambiguous results with regard to whether these species show metacognitive control and monitoring. Inman and Shettleworth (1999) exposed pigeons to a delayed matching-to-sample task where the Uncertain option resulted in a relatively small reward, whereas correct matching responses led to large reward and incorrect responses led to punishment. Even though their matching accuracy decreased with longer delays, the pigeons failed to use the Uncertain response. In a second experiment where pigeons were allowed to reject a difficult trial (similar to Hampton 2001), they again failed to utilize that response. Teller (1989) and Kuroda et al. (2014) demonstrated that pigeons would use an Uncertain response in a DMTS task, but they could not conclusively demonstrate that external stimulus cues (i.e., the delay intervals) were not controlling the use of the Uncertain option. Thus, to date, there is no conclusive evidence that pigeons demonstrate uncertainty monitoring, although there are some suggestive lines of evidence (e.g., Castro and Wasserman 2013).

Rats were trained to classify the duration of auditory streams as being either short or long. For those durations closest to the divide between a true “long” duration and a true “short” duration, the rats were most likely to decline completing the trial (Foote and Crystal 2007). In a second experiment, rats again classified these sound durations, but they were given trials in which they were forced to make a classification (i.e., they could not escape), or forced to replay the sound (i.e., they had to decline making the primary responses), or they were allowed to choose between taking the test or replaying the sound. Here, the evidence for a metacognitive pattern of responding was mixed. Rats did show the accuracy difference that would be predicted by a metacognition account for forced-repeat and choice-repeat trials. However, the other features that would be expected if metacognitive monitoring was occurring were not readily evident.

Ambiguous outcomes from metacognition tests also can occur for primate species. Beran et al. (2009) designed a sparse-dense discrimination task for capuchin monkeys with an Uncertain response option used to decline a difficult trial (as in Smith et al. 1997). Beran et al. also included a control condition where instead of an Uncertain option there was a “Middle” option that was designated as correct for those samples that had intermediate pixel densities between the sparse and dense regions. Although the monkeys were easily able to use the Middle response, only one of the six monkeys used the Uncertainty response – and even then the one successful monkey might have confused the Uncertainty response as a Middle response. Basile et al. (2009) replicated with capuchins Call and Carpenter’s (2001) procedure where food was visibly baited or concealed and searching for the food would demonstrate uncertainty monitoring. Most monkeys did not search for the unknown food items, and when the search effort costs were increased none of the monkeys searched for food. Paukner et al. (2006) also arranged a food search task where capuchin monkeys had to search tubes for baited food. Though some monkeys did search the tubes, they also demonstrated search behavior under conditions where the tubes were transparent or when the

tubes were bent and their inspection would not reveal any useful information. Thus, the appearance of information-seeking behavior in that study was likely due to other reasons (e.g., manipulation of an enrichment apparatus).

To summarize, there is evidence that dolphins, macaques, orangutans, and chimpanzees will demonstrate metacognitive awareness of the likelihood that they know the correct response (uncertainty monitoring), and they utilize that awareness to adapt behavior to improve performance through behaviors such as information-seeking responses (cognitive control). Although pigeons and rats have yet to reliably demonstrate that capacity in a diverse range of tasks and capuchin monkeys appear to demonstrate a metacognitive ability only if the procedure is calibrated to discourage their propensity play the odds, future research efforts may expand the phylogenetic map of metacognitive capacities. The next section discusses the plausible processes and mechanisms that may govern animals’ performances in these tasks.

Controversies About Animal Metacognition

The results outlined above suggest an enticing possibility that the expression of animals’ uncertainty monitoring stems from a similar psychological state shared with humans – thus, animals may also have similar conscious metacognitive experiences. However, such an attribution could be a dangerous overgeneralization that imposes an anthropocentric view on animal psychology. The principal alternative explanation to a metacognitive system is associative conditioning processes that rely on reinforcement, punishment, and stimulus control (e.g., Jozefowicz et al. 2009; Le Pelley 2012). Before a theory of the evolutionary emergence of a metacognitive system that has culminated in adult human capabilities can be advanced there are a variety of associative hypotheses that have needed to be addressed (e.g., Crystal 2014; Kornell 2014).

First, the expression of the uncertainty monitoring could be due to external environmental

stimuli that cue the subject to make an uncertainty response. For instance, macaques may have selected the uncertainty option in a difficult perceptual discrimination trial because in the absence of a clearly correct response the monkeys discriminated their latency to make a response. While Smith et al. (1995) noted that this was a possibility, there is evidence against this explanation given by Shields et al. (1997). Shields and colleagues did not observe a correlation between response latency and the utilization of the Uncertainty option. Alternatively, it is possible that some procedural cue (e.g., the sample stimuli that are often predictive of a timeout in a discrimination task or the delay interval in a DMTS task) occasioned the beneficial use of the Uncertainty option. Indeed, there is evidence that this can be the case. Teller (1989) evaluated metamemory in pigeons and observed that Uncertain responses were used at long delay intervals in the DMTS procedure. The Uncertain response appeared to be due to the pigeons learning the associative contingency of long intervals and Uncertain responses rather than some endogenous expression of uncertainty monitoring. However, this is not always the case. The Hampton (2001) metamemory task occasionally produced a discrimination trial without a sample stimulus where the delay interval was very short, and the monkeys still used the Uncertainty response. Washburn et al. (2010) had macaques work on a DMTS task with brief delay intervals where the monkeys could frequently successfully match. On some trials, the experimenters introduced transcranial magnetic stimulation (TMS) during the delay interval to disrupt discrimination performance by blocking memory for the stimulus. The TMS disrupted discrimination accuracy and increased the likelihood that the monkeys would use the Uncertain response. Thus, despite the procedural aspects being held constant, artificial methods (such as TMS) to disrupt discrimination performance still resulted in the utilization of the Uncertainty response. Smith et al. (2010) exposed macaques to a discrimination task that simultaneously varied the cue difficulty and the type of discrimination being asked when pixels were presented on a screen (sparse or dense samples, cyan or yellow

samples, top or bottom color contrast divider, and left or right color contrast divider; Fig. 4, top panel). The monkeys generalized the use of the Uncertainty response for difficult trials across all tasks, despite there being no single cue that signaled that an Uncertainty response would be efficient (Fig. 4, bottom panel). Perhaps most convincingly, Kornell et al. (2007) arranged a variety of discrimination tasks where correct responses resulted in +3 tokens, incorrect responses resulted in -3 tokens, and the Uncertain response resulted in +1 token. Once 12 tokens were earned then the monkeys would earn a pellet. Monkeys worked on a circle size discrimination task when the metacognitive contingencies were being initially trained. Subsequently, the monkeys worked on a serial recall task with the metacognitive contingencies included but not explicitly trained for this task. The use of the metacognitive response spontaneously transferred from the perceptual task to the serial recall task without training. This demonstrated that the training of the use of the Uncertainty response was not isolated to the specific task that it was originally trained under but rather generalized across procedures. This generalization goes against strict associative accounts for the use of the Uncertainty response, since the response still occurred under different experimental conditions and with very different external cues correlated with a potential difficult trial. Also, the generalization of the Uncertainty response from use in a perceptual task to use in a metamemory task suggests that metacognition and metamemory processes are tied to a similar underlying process.

Second, it is possible that the expression of uncertainty monitoring (rejecting a difficult trial, information seeking, or confidence judgments) is artificially reinforced behavior that does not reflect (or is otherwise influenced by) a metacognitive mechanism. This confound to hypotheses that suggest uncertainty monitoring is due to a conscious process of knowing can be difficult to address. Any conscious metacognitive process would likely develop because it aids in the organisms' adaptiveness to the environment and as such should aid in the attainment of rewards and the avoidance of aversive outcomes. Such a

Metacognition, Fig. 4 Monkeys' performance in four psychophysical tasks. The *top* part of the figure shows the four types of discrimination, and the *bottom* graphs correspond to performance on each of those tasks. In the graphs, the horizontal axis indicates the trial level. The percentage of trials receiving the uncertainty response at each level is

shown (*filled triangles*) along with the percentage of correct responses made when animals completed trials with a primary discrimination response (*open squares*) (From Smith et al. (2010). Copyright 2010 by Springer. Reprinted with permission.)

mechanism would be distinct from reinforcement processes, but by using behavioral measures it would be difficult to distinguish between the two. Regardless, there is some evidence to suggest that uncertainty monitoring is not simply a product of reinforcement applied to the uncertainty response. Reinforced behavior does not occur in a vacuum; the behavior must either occur in a discriminated context where the behavior has traditionally resulted in reinforcement or (prior to stimulus control) it should occur indiscriminately across contexts. As discussed above, the expression of uncertainty monitoring occurs under conditions where the probability of making a correct response is low and is not related to any measurable external sources of stimulus control. If the uncertainty response was directly reinforced, then there is no clear reason to predict that it would occur in the absence of external stimulus cues while also reliably occurring under conditions where an incorrect response is likely. Though some procedures have arranged an incentive for using the Uncertainty responses (relatively smaller food reward, Hampton 2001; progression to an easier trial, Smith et al. 1997), the efficient use of the Uncertainty response occurs under conditions where there are no programmed rewards for using it other than to avoid the present trial (e.g., Beran et al. 2006).

In order to even further dissociate the reinforcement from the use of the uncertainty response Smith et al. (2006) prepared a sparse-density pixel discrimination task that deferred the consequences of the responses until the end of a 4-trial block. No response on a single trial resulted in feedback, and at the end of the block the sum of pellet rewards for correct responses and timeouts for incorrect responses were delivered, not in the order of trial presentation, but with all rewards first and then all timeouts. In this way, the monkeys could not directly track each response to its immediate outcome. The use of the Uncertain response option made no contribution to the post-block feedback and effectively rendered the associated trial inconsequential. The question was whether in the absence of this direct feedback the monkeys would continue to use the Uncertain response when facing a

difficult trial. One monkey did, and furthermore the use of the Uncertainty response was well predicted by the subjectively experienced difficulty of trial stimuli rather than the objectively defined difficulty (Fig. 5). In other words, uncertain responses often were made to objectively easy trials and incorrect responses (with few uncertainty responses) were common to objectively difficult trials, because the monkeys were tricked into thinking that truly easy trials were the harder ones they faced. These data support the claim that uncertainty monitoring operates from a process that detects difficult discriminations rather than a process that requires tight feedback (reinforcement or punishment) applied to an Uncertainty response.

Third, the Uncertainty response to escape a trial might be an avoidance response emitted when the sample has been historically correlated with a timeout punishment. Thus, the sample on a difficult trial would not affect any uncertainty monitoring but would be “bad news” because punishment follows it, and therefore the Uncertainty response would remove this bad news sample. Though reasonable, this explanation would not easily account for the expression of uncertainty monitoring using other procedures such as confidence movements corresponding with a correct response or differential cashing out responses to the same stimuli as a function of how many tokens were at risk (e.g., Zakrzewski et al. 2014). This explanation also does not account for some procedures using the Uncertainty response to escape a trial. Shields et al. (1997), for example, did not present difficult trials with a singular sample but rather the relative discriminability between two samples varied the difficulty without allowing any one stimulus feature to be correlated with a timeout. In the absence of a singular stimulus feature correlated with a timeout, it is difficult to isolate what external stimulus cue the monkeys would be avoiding.

Taken together, the weight of the evidence suggests that uncertainty responses are not easily explained by evoking a variety of conditioning processes. However, evidence against particular conceptualizations of an associative explanation does not endorse alternative cognitive

Metacognition, Fig. 5 (a) The performance of a rhesus monkey in the sparse-dense discrimination from the deferred feedback task. The horizontal axis indicates the density bin of the box. The sparse and dense responses, respectively, were correct for boxes at density bins 1–13 and 14–26. The *open circles* show the proportion of trials attempted that were answered correctly. The *dark circles* show the proportion of trials receiving the uncertainty response at each density bin. (b) The monkey's performance in the same task, but now showing his proportion of trials declined in each density bin plotted against his

proportion of trials answered correctly. (c) The monkey's performance is shown in the same task, but now showing separately his use of the sparse and dense responses (*open circles* and *open triangles*). (d) The monkey's performance in the same task, but now showing his proportion of trials declined in each density bin plotted against the decisional distance of the bin from his decisional breakpoint (bin 9 = 0; bins 8 and 10 = 1; bins 7 and 11 = 2, etc.) (From Smith et al. 2006. Copyright 2006 by the American Psychological Association. Reprinted with permission.)

explanations by default. Strong evidence that uncertainty monitoring is a product of a meta-cognitive system comes from Smith et al. (2013). They assessed whether uncertainty monitoring requires cognitive resources to efficiently reject difficult trials. They arranged a DMTS task and then embedded a sparse-dense discrimination trial within the delay interval of the DMTS task. The sparse-dense task either had an uncertainty option associated with it or a

Middle option that replaced the Uncertainty option. They found that the use of the Uncertain option was greatly underutilized, while the use of the Middle option was unaffected. This dissociation of Middle versus Uncertain responding in the context of the concurrent DMTS task is explained by claiming that uncertainty monitoring requires additional cognitive resources to function efficiently, while the reinforcement-maintained Middle response did not. Such results suggest that

Middle and Uncertain response are fundamentally different processes and that uncertainty monitoring is more cognitively taxing.

Another strong and compelling set of results comes from Basile et al. (2015) who evaluated seven hypotheses about alternate accounts to a metacognitive interpretation of rhesus macaque performances during a series of computerized tasks. In these tests, monkeys chose either to take memory tests immediately or to see the answer again before proceeding to the test, a response that could be made when monkeys were aware of weak or nonexistent memory sufficient for taking the test. Basile et al. examined alternate explanations grounded in behavioral cue association, rote response learning, expectancy violation, response competition, generalized search strategy, or postural mediation. None of these accounts could explain the monkeys' pattern of taking tests where they chose to see the answer when memory was poor, either from natural variation or experimental manipulation, and chose to take the test when memory was strong. In addition, there was limited evidence that monkeys also may have monitored the fluency of their memory access, providing an overall pattern in that study that suggested that rhesus monkeys use their memory strength as a discriminative cue for information seeking (also see Templer and Hampton 2012).

Conclusion

Although focused criticisms have been offered in this area of research, often with the consequence of sharpening the quality of the debate and the quality of the methodologies that have been developed, a consensus seems to be emerging that some species may monitor states of knowing and perceiving and may control information use and acquisition to serve adaptive decision-making. The precise mechanics underlying this cognitive process, however, still remain undefined, and there are plenty of future experiments still needed to discover the nature of metacognitive system(s) across species and how metacognitive processes may interact with other systems. Those efforts

will have implications for evolutionary psychological science but also for developmental science and cognitive science more broadly. It is also important to note that the presence of metacognitive processes in nonhuman species does not necessarily mean the presence of human-like conscious experiences of those metacognitive processes. Metacognition is not a "switch" in minds, that is either on or off, and when in on mode equivalent in all instances and across all individuals. Metacognition is a regulatory suite of control and monitoring processes, each of which is subject to competition for attention, resource-dependent in terms of how efficiently such control and monitoring processes can occur, and prone to the influences of other mechanisms, both cognitive and associative. That a monkey, a chimpanzee, or a rat can show analogous control and monitoring capacities to those shown by adult humans does not require the assumption of homologous phenomenology across those species. Nonhuman animal metacognition research may illustrate only the glimmerings of human-like conscious states of knowing and not knowing in other animals, but even such glimmerings highlight from where our own fully conscious metacognitive states may have begun. Such insights can provide valuable information to evolutionary psychological science.

Definition

Conceptual understanding that results from mapping, projection, compression, and elaboration of elements from different ideas, different mental spaces, and different concepts.

Introduction

The mental operation of connecting or combining different concepts has been researched under many names over the last 3,000 years. The rhetorical tradition (Aristotle 1995) uses the terms “metaphor,” “metonymy,” “analogy,” “parable,” and “simile” (μεταφορά, μετωνυμία, ἀναλογία, παραβολή, παρομοίωση). Modern cognitive science has contributed the terms “convolution” (Thagard and Stewart 2011), “blending,” and “integration.”

The system of mental principles that guides and governs these operations is complex. Research on the subject stretches back to at least Aristotle, who wrote that “to do metaphor well is to see (*consider*) likenesses” (*Poetics*, XXII, 17; Aristotle 1995). When Aristotle defines metaphor as the transfer of a noun from one thing to another, he means transfer motivated by conceptual relations – either of category (genus to species, species to genus, species to species) or of analogy. Conceptual connection drives linguistic figuration: “To scatter seed is to sow, but there is no word for the action of the sun in scattering its fire. Yet this has to the sunshine the same relation as sowing has to the seed, and so you have the phrase ‘sowing the god-created fire’” (*Poetics* XXI, 14; Aristotle 1995).

The last century has witnessed constant and energetic investigation of the principles of the mental operations of concept combination, with emphasis on human distinctiveness. C.S. Lewis wrote in 1936 that understanding one story figurally in terms of another story belongs not principally to expression and not exclusively to literature, but rather, *to mind in general*, as a basic cognitive instrument (Lewis 1936, p. 44). By “mind,” he meant, of course, the cognitively modern human mind. The history of these traditions of

research is reviewed in (Cacciari et al. 1998; Turner 2005). Fauconnier and Turner (2002) present a review of the current state of research into such principles.

Evolutionary Psychology

Abilities for mental combination of concepts present an open scientific problem for evolutionary psychology. Remarkably, this combination typically involves concepts that would be maladaptive for a mind ever to *confuse* or to misconstrue as *identical*. For example, one of the most fruitful such patterns of combination for human beings consists in understanding another organism as having a full mind, by taking what we can know of that other organism (its appearance and perceptible behavior) and blending it with things we can know of only ourselves: when we move that way, it is because of pain; when we look in that direction, it is because something has caught our attention; and so on. By such complex combination and adjustment, we can have a very full concept of another person. Other species have some of this ability, and research into concepts other species can achieve of other minds has increasingly discovered subtlety (Call and Tomasello 2008).

Still, by all accounts, human beings are in various ways incomparably beyond other species, including chimpanzees and domestic dogs, in these abilities. Human beings do not confuse themselves with another person; they are not deluded; they do not make the mistake of thinking that these two quite different things are identical. But they can combine the concept of themselves with the concept of another person not only to create a concept of a full mind for another person but also to imagine alternative versions of themselves, and even to blend their current self with memories of their previous selves to create the amazing concept of a personal identity, a character that persists over decades. Without confusion, human beings routinely combine concepts that should not be confused.

How could these abilities have evolved? Deacon, in a range of publications (e.g., Deacon 2010), has proposed a process of human self-

domestication, resulting in a relaxation of selection pressure that made it possible for such abilities to arise and be unmasked. Fauconnier and Turner (2002) and Turner (2014) have provided reviews of some possible evolutionary explanations – all highly speculative – of these abilities. They have proposed that capacities for connecting and combining concepts have been evolving for a long time and that human beings show only a relatively slight increase in this ability but that a slight change in causes can make a dramatic difference in effects: cognitively, modern human beings are able to perform the most advanced form of concept connection and combination, and this ability is indispensable for a great range of downstream cognition and behavior – language, art, music, mathematical insight, scientific discovery, religion and ritual, fashion, advanced social cognition, advanced tool conception, and so on.

The known archeological record makes it clear that cognitively modern human beings have had these abilities for at least roughly 50,000 years; claims for earlier capacity would require more evidence, although these claims are not uncommon. For example, archeological discoveries dating from 175,000 years ago in the Bruniquel Cave in southwest France led to speculation that their purpose was symbolic ritual behavior among Neanderthals. But other interpretations view them as used for routine purposes. Absent a time machine or a radically altered archeological record, it is unclear how such questions could be definitively resolved on archeological evidence.

Conclusion

To the author's knowledge, there is no genetic research dedicated directly to explaining the evolution of these cognitively modern mental operations, although there are hints in population genetics work on genetic variation and language about increasing capacity. There is also the hope of discovering something about the evolution of these cognitively modern mental operations by looking for neural substrates, as reviewed in Turner (2014). But these mental operations of

concept connection and combination are higher order, depending upon the activity of many other operations at the same time; they seem to operate over all conceptual domains and, constantly, in the backstage of cognition. Accordingly, it is difficult to see how current brain imaging techniques could provide research instruments for pursuing the evolutionary question. But they are of very recent invention and continue to be improved every decade. As always, we await the improvement of archeological, genetic, and neuroscientific techniques for the study of the cognitively modern human mind, including its ability to connect and combine concepts.

Meta-tool

Ivo Jacobs and Mathias Osvath
Lund University, Lund, Sweden

Definition

A tool used simultaneously with a second tool to increase the efficiency or effectiveness of the second tool, where the first tool (the metatool) acts directly on the second, without being used in the manufacture of the second tool. (Shumaker et al. 2011)

Introduction

A chimpanzee searches the tropical forest of Bossou, Guinea, for suitable stones. She has collected oil-palm nuts, which can only be opened with tools. Having localized a large tree root, she places a nut on it and strikes it with a stone held in her hand. This is called *pound* or *hammer* tool use, which amplifies the force exerted on the nut through the use of a stone tool. However, her nut-cracking attempt fails because the wood is too soft. She therefore looks for a heavy, flat rock, which she puts on the ground to serve as an anvil. In contrast to the root, this is a tool because she directly manipulates it prior to use and is responsible for its effective orientation. Together, the hammer and anvil form a *tool composite*, defined as two tools used simultaneously to achieve a single outcome. Unfortunately, she fails again because the anvil stone is unstable. She therefore places a smaller stone underneath it, like a wedge, resulting in a stable, horizontal surface suitable for nut cracking (see Fig. 1). This is a subcategory of tool composites called *meta-tool* use; the small stone does not produce but increases the effectiveness of the anvil and both are used simultaneously (Shumaker et al. 2011).

Meta-tool, Fig. 1 Meta-tools in the form of anvil wedging by Bossou chimpanzees. Shown on the *left* is the hammer stone and on the *right* the anvil supported by two wedges. Reprinted from Journal of Human Evolution, Vol. 55, Carvalho et al., Chaînes opératoires and resource-exploitation strategies in chimpanzee (*Pan troglodytes*) nut cracking, 148–163, Copyright (2008), with permission from Elsevier. <http://www.sciencedirect.com/science/journal/00472484>

How Widespread Is Meta-tool Use?

The term meta-tool use was first coined by Matsuzawa (1991), involving an old chimpanzee female who was provisioned with nuts and stones at an experimental site. He defined it as using a tool for another tool, but this is very broad and would include other tool combinations, such as using a tool to acquire another tool (sequential tool use) or using a tool to modify another tool (secondary tool use). Shumaker et al.'s (2011) definition considers meta-tool use as distinct from other categories involving multiple tools.

With this more restrictive definition, only a few species have been observed to use meta-tools. It has been mostly documented in chimpanzees. *Anvil propping* (the example from the introduction) has since the initial report also been observed in other age-sex classes of the same population (Carvalho et al. 2008; Hayashi 2015; Matsuzawa et al. 2011; Whiten et al. 1999). In one case, two stone wedges were found underneath an anvil stone (Carvalho et al. 2008; see Fig. 1). It is estimated that anvil propping occurs once every 100 visits to the experimental Bossou site and remains stable over different study periods but is more frequent in uneven terrain (Biro et al. 2010).

Chimpanzees and orangutans have been observed to use leaf sponges or paper to absorb liquids, which they then retrieve with a stick (Shumaker et al. 2011; Whiten et al. 1999). This is meta-tool use because although the liquids could be reached with a stick alone, the leaf sponge or paper greatly increases its effectiveness. Capuchin monkeys sometimes use hammers and chisels. Chisels could be used to break through or remove lids and covers, and the stone hammers allow the capuchins to exert more force. Similar meta-tool use involving a hammer and chisel was observed in a home-reared chimpanzee and a zoo-housed orangutan (Shumaker et al. 2011).

The occurrence of meta-tool use is limited outside of the primate order. Hermit crabs occupy empty shells of sea snails for protection. These shells are tools that the crab can make more effective by applying anemones to them for additional protection. In one experiment, this meta-tool use stopped all attacks by octopuses after initial attempts, whereas all hermit crabs inhabiting shells without anemones were eventually consumed (Ross 1971). Satin bowerbirds attract females by decorating bowers, which they construct for this purpose. Some males paint their bowers with charcoal by using a bark wad as a brush. This brush can be considered a meta-tool if it makes applying paint easier or faster (Shumaker et al. 2011).

Anvil Propping

No systematic studies on the cognition underlying meta-tool use have been done, but its complexity is inferred from the number of actions or movable objects involved, the long development to reach proficiency, and the selectivity of tool types. Matsuzawa (1996) mapped the complexity of chimpanzee tool use by developing a hierarchical tree structure as a kind of action grammar. The level is determined by the number of simultaneous relationships between objects used. For example, picking up a nut is level 0 because the object does not relate to other objects. Using a hammer to smash a nut on an anvil is level 2: the nut rests on the anvil (one relationship) and is smashed by the hammer (one relationship). Meta-tool use is level 3 because it introduces another relationship—

that between the anvil and the wedge. Some researchers believe that anvil propping by chimpanzees is the most complex form of tool use exhibited by wild nonhuman animals (Hayashi 2015; Matsuzawa 1996) and that causal understanding is involved if wedge stones are intentionally used to level anvils (Matsuzawa et al. 2011).

Nut cracking is a skill that takes many years to fully develop. Chimpanzee juveniles in Bossou first succeed between 3.5 and 7 years old and reach proficiency between 8 and 14 years. There appears to be a sensitive ontogenetic phase in which nut cracking must be learned, or else it does not develop at all (Matsuzawa et al. 2011). Adults exhibit selectivity in what tools to use; hammers are typically lighter and smaller than the anvils. This is a sign of their behavioral flexibility that relies on their cognitive abilities (Carvalho et al. 2008). They adjust the height to which the hammer is lifted and the force with which to strike, depending on the nut type, hammer weight, and anvil surface. If their tool use is ineffective, they reposition their tools or switch to others (Matsuzawa et al. 2011).

A 2-year-old infant kept in captivity succeeded at such a young age because it had more experience manipulating objects and watching adults crack nuts (Hayashi 2015). Social learning appears to be an important factor in learning this behavior. Some populations do not crack nuts despite sufficient ecological circumstances, which supports the argument that it is a culturally transmitted behavior (Whiten et al. 1999). The type of nut to crack seems also to be socially learned. When unfamiliar nuts were introduced into the Bossou community, they were mostly ignored even by expert nutcrackers, but one female immediately cracked them. It is likely she migrated at an early age from a neighboring community where these kinds of nuts are commonly cracked. After prolonged exposure to these unfamiliar nuts, more individuals attempted to crack them, and the behavior slowly spread through the community while exploratory behaviors decreased. All juveniles attempted to crack artificial wooden balls that resembled unknown nuts, which suggests that novel nut types may initially

be discovered to be exploitable food sources through the general manipulative and explorative tendencies of juveniles (Matsuzawa 2001; Matsuzawa et al. 2011).

The development of anvil propping has not been studied in detail due to its infrequent occurrence. The youngest age at which a wild chimpanzee has been observed to use such meta-tools is 6.5 years. Children of the Bossou village first succeeded at a similar age (Matsuzawa 2001; Matsuzawa et al. 2011). It is likely that the use of anvil propping in chimpanzees is learned through similar processes as hammer-anvil use. Using these tools is necessary for nut cracking, but meta-tool use is only rarely beneficial. If an anvil is too unstable or slanted, it can be exchanged for another, rotated, flipped over, or moved to another location with a more suitable substrate. Wedging a stone under the anvil may be a final recourse, one that is infrequently used because it requires an additional object and an unusual action (Matsuzawa et al. 2011). One line of evidence for this explanation is that chimpanzees transport anvils and hammers more frequently than wedges (Carvalho et al. 2008). It should also be noted that finding meta-tools does not necessarily point to purposive behavior. In some cases chimpanzees rotated an anvil to find a stable position and accidentally flipped it on top of another stone (Hayashi 2015).

Conclusion

Meta-tools are rarely used by nonhuman animals. One reason for this may be that they are often unnecessary. Simpler solutions are then preferred that do not involve complex relationships and additional objects. However, only little research has been done on meta-tool use, and much of it is confused with other categories that also involve multiple tools due to unclear definitions. Further investigations should establish which other species use meta-tools – in conditions that are ecologically relevant or experimentally induced – and may unravel its cognitive requirements when other solutions are unavailable.

Methods and Enduring Impact of Behaviorism

James W. Diller

Department of Psychological Science, Eastern Connecticut State University, Willimantic, CT, USA

Synonyms

[Applied behavior analysis](#); [Experimental analysis of behavior](#); [Single-subject experimental design](#)

Definition

Behavior analysts rely on single-subject experimental designs in which variables that control behavior are directly manipulated and their effects are directly observed. Because of the high degree of experimental control and powerful intervention effects, behavior analysts prefer visual analysis of data over statistical analysis.

Introduction

The methodology used in behavior analysis is a defining feature of this field. Fundamentally, behavior analysts use experimental methodologies in which direct control over independent variables can be exerted. Behavior analysts manipulate these variables to measure their direct impact on behavior (cf. Sidman 1960). Rate of responding is commonly used by behavior analysts, but other dimensions of behavior are also measured. For example, latency to respond, or percent correct, or the number of intervals in which a response occurs could all be used, depending on the target behavior under consideration (Cooper et al. 2007). The application of these research methods has produced a behavioral technology (i.e., a set of procedures that can reliably be used across settings, individuals, and target behaviors) that has been used to solve behavioral problems in humans and nonhuman animals.

Methodology

The science of behavior analysis focuses on observable behavior and does not appeal to theories that describe the events at another level of discourse (e.g., physiology, mental events; cf. Skinner 1950). This emphasis on behavior itself is at odds with what Tooby and Cosmides (1989) saw as the more important goal of “the investigation and characterization of the innate psychological mechanisms that generate and regulate behavior” (p. 32).

Rather than relying on between-groups experimental designs with large numbers of subjects and statistical inference, behavior analysts prefer single-subject (or within-subjects) designs with experimental control over statistical control. That is, manipulation of controlling variables yields functional relations between their selected independent variables and behavior (their dependent variable). Behavior analysts generally reject statistical analyses (cf. Perone 1999; Sidman 1960) and instead use visual analysis of data. Visual analysis involves systematically examining graphic displays of data to identify how behavior has changed and the extent to which the independent variable or environmental manipulation is responsible for that change (Cooper et al. 2007). To effectively use visual analysis, behavior analysts must select and manipulate variables that directly impact the behavior under study.

Instead of comparing between groups, behavior analysts usually take repeated measures, relying on the individual subject to serve as his or her own control. This tactic reduces the amount of variability that is necessary to control or explain, allowing for powerful demonstration of experimental effects (cf. Sidman 1960). The establishment of a baseline is the first step in a single-subject experimental design.

The baseline is a pre-intervention measure of the behavior of interest. Generally, the baseline phase lasts until behavior stabilizes or reaches a steady state (i.e., there is limited variability in the data, and there is no increasing or decreasing trend). Because behavior analysts attribute behavior change to environmental events, it is assumed that the steady behavioral state would continue until an environmental change occurs; given a consistent environment, behavior should continue, unchanged. This assumption of steady-state methodology allows for the meaningful comparison of subsequent intervention phases with the established baseline. Of course, there may be circumstances that prohibit achieving stability; for example, if the target behavior is too dangerous to continue, as with self-injury, an intervention may be applied before stability is achieved.

Most single-subject experimental designs involve the administration of an intervention following the baseline. For example, if the target behavior is occurring less often than is desired, a reinforcement technique could be employed to strengthen the response. Behavior is then measured for some period of time, usually until stability is regained. A return to baseline conditions (i.e., the withdrawal of the reinforcement) can allow for the assessment of the durability of the behavior change. This baseline-intervention-baseline pattern comprises the simplest single-subject design, the reversal design.

More complex variations of the reversal design can also be employed, depending on the research question. If a phenomenon's generality is of interest, a multiple-baseline design could be used, in which more than one baseline is sequentially established across individuals, participants, or behaviors. By applying the intervention in a staggered fashion (i.e., extending some of the baselines while measuring change in the targeted behavior, individual, or setting), it is possible to demonstrate the generality of an intervention's effectiveness. Maintaining baseline conditions for the other settings (or individuals or behaviors) allows for the demonstration of causality—that is, behavior should only change when the intervention is introduced and not before.

Not all procedures involve a stable baseline before changing environmental events. A multielement (or alternating-treatment) design involves rapid transitions between experimental conditions. Multielement designs are frequently employed when applied behavior analysts conduct a *functional analysis*, a technique which allows the behavior analyst to identify the reinforcers that maintain a particular response. Depending on the function of the behavior (i.e., the relevant reinforcer), an appropriate intervention can be selected to decrease the occurrence of the target response (cf. Iwata and Dozier 2008). Common reinforcers include attention, escape from a situation, access to goods or edibles, or sensory stimulation (Cooper et al. 2007). These consequences may derive their reinforcing efficacy because of the evolutionary history of the organism under study.

If the goal of the intervention is to gradually change (i.e., increase or decrease) behavior to reach a goal, a changing-criterion design could be employed. In this type of design, the experimenter sets a goal level of responding. For example, a teacher may say that a student should answer ten questions correctly on a ten-item quiz. As this goal might be beyond the current performance of the student, a lower goal (e.g., six correct answers) could be set initially. Meeting that goal would result in the delivery of a reinforcer. After a few sessions of successfully meeting the initial goal, the goal can be gradually increased (e.g., seven correct responses) for another block of sessions. Beginning with a goal that is attainable for the learner and gradually increasing the requirement make it more likely that they will successfully achieve the desired performance.

Despite the strengths of single-subject methodologies for identifying variables that directly influence behavior for a particular organism, there are some potential limitations to these designs. Not every relevant variable can be manipulated, due to practical or ethical constraints; this limitation requires that some questions be answered using correlational or between-groups experimental designs. Additionally, the generality of interventions might be limited, since only a few organisms are used in this type of research. However, replication or the use of a multiple-baseline design could help to ameliorate this concern. The influence of any intervention would need to be evaluated on the target individual before knowing that it is effective. This functional, individualized approach to scientific inquiry and intervention epitomizes the behavior-analytic approach. Whereas this approach is well suited for behavior-analytic questions of environment-behavior interactions, it may be less appropriate to answer the questions of “the discovery and characterization of psychological mechanisms as adaptations” (Tooby and Cosmides 1989, p. 32), since behavior analysts would refer more to proximate, immediate environmental events as causal explanations instead of psychological mechanisms. However, the search

for individual-level explanations for group-level processes (Tooby and Cosmides 1989, p. 45) might benefit from the use of single-subject experimental designs.

Impact

Despite the advent of cognitive psychology and the continued reliance on statistical analysis by mainstream psychology, the discipline of behavior analysis continues to be vibrant. Since 1957, the *Journal of the Experimental Analysis of Behavior* has published basic behavior-analytic research. The *Journal of Applied Behavior Analysis* began its publication in 1968; this field uses the techniques of behavior analysis to solve socially significant problems (cf. Baer et al. 1987).

Although applied behavior analysis is known predominately as a technique for providing treatment to individuals with developmental disabilities, there are a host of other applications that have made remarkable contributions to improve life for people across the developmental spectrum. Using the techniques of behavior analysis, researchers and practitioners have reduced self-injurious behavior (cf. Iwata and Dozier 2008), detected landmines and tuberculosis (Poling et al. 2011), reduced drug abuse (Alessi and Petry 2013), and promoted environmental sustainability (Lehman and Geller 2004).

Conclusion

The principles and methodologies pioneered by B. F. Skinner and his fellow behavior analysts have led to the ability to predict and influence behavior of human and nonhuman animals. Wherever there are behaving organisms, their behavior can be understood, and the principles of behavior analysis can be applied to help them live more effectively.

Methods of Filicide

Lauren Summerville
Cincinnati Children's Hospital, Cincinnati,
OH, USA

Synonyms

[Child homicide](#); [Childhood fatalities](#); [Family violence](#); [Infanticide](#); [Neonaticide](#)

Definition

The murder of a child by a parent or stepparent.

Introduction

It would seem as though filicide is a flagship example for a behavior does not seem to fulfill an ultimate goal of evolution: the passing of one's genes onto the next generation. This section seeks to answer the *who* and *with what* questions, rather than the *why* question of filicide. The method in which a parent – or stepparent – uses to murder their child has discrete features and is a source of information into the relationship this person has with the child.

Methods of Filicide

A distinction lies between how different individuals commit filicide: whether or not that child shares genetic material with that individual. In a pivotal article, Daly and Wilson (1994) found stepfathers were more likely to commit filicide by beating and bludgeoning than genetic fathers, who were more likely to use faster methods of killing by shooting or strangulation.

Furthering this line of work, Weekes-Shackelford and Shackelford (2004) analyzed homicide reports for instances of filicide, the perpetrator, and the method of killing in the United States between 1976 and 1994. Children under the age of five were eight times more likely to be killed by a stepfather than by a genetic father and three times more likely to be killed by a stepmother than a genetic mother. For the method of killing, beating by a stepparent comprised 93 % of filicides compared to 67.6 % by genetic parents. For suffocation-drowning-strangling, 5 % of filicides by stepparents utilized this method and 18 % of filicides by genetic parents. For shooting, 1 % of filicides by stepparents utilized this method and 5.8 % of filicides by genetic parents. Stepparents are more likely to choose a method of filicide that is aggressive, violent, painful, and prolonged. Genetic parents are more likely to choose a method that is quick and relatively painless.

Age of the victim can be a factor. Lewis et al. (1998) discovered older children were

significantly more likely to be killed with weapons (e.g., knife, gun) than younger children. Moreover, psychotic women were more likely to utilize weapons to kill their children than non-psychotic women. Young children (less than 10 years of age) tend to be bludgeoned to death, smothered, drowned, or strangled – potentially due to the relative ease to execute these acts on their smaller bodies, negating the need for a lethal weapon. It was only when the woman was psychotic (suffering from hallucinations and/or paranoid delusions) that she would use a lethal weapon on her very young child.

The duration of the act is also a factor when the perpetrator chooses a method. Debowska et al. (2015) conducted a review of filicide in the United Kingdom. Their results supported the notion that genetic parents utilized methods that hastened death, such as carbon monoxide poisoning, strangulation, or drowning while stepparents used methods that prolonged the event, such as battery. In Taiwan, an uptick in mothers burning charcoal to produce lethal levels of carbon monoxide as a means to achieve maternal filicide-suicide was discovered. The inhalation of the gas results in what is colloquially known as a “painless death,” thereby becoming a popular method of filicide in the country (Yasumi and Kageyama 2009). Indeed, Bourget and Gagne' (2002) discovered maternal filicides in Quebec between 1991 and 1998 were most commonly committed by carbon monoxide poisoning, firearm, strangulation, or drowning. The majority of these mothers suffered from major depressive disorder.

The mere presence of an unrelated adult can significantly increase a child's odds of being murdered. Schnitzer and Ewigman (2005) discovered children less than 5 years old living in households with unrelated adults were almost 50 times as likely to die of inflicted injury than children residing with both biological parents in Missouri between 1992 and 1999. The majority of these deaths were caused by shaking or striking that resulted in head, thoracic, abdominal, or multiple traumas – followed by suffocation, firearm, poison, or burns. In 2007, a Canadian study revealed filicide by a stepparent was common and the method of killing involved

protracted abuse and neglect prior to death by beating (Harris et al. 2007).

Another method of filicide is the phenomenon of *unintentional fatality* – death as a result of an event that is an accident. Examples of events precluding childhood death include road accidents, falls, suffocation, burns, drowning, or poisoning. Vigilance against threats of these kinds towards children would be evolutionarily advantageous and ever present in parents hoping to secure the safety and well-being of their genetic off-spring. Tooley et al. (2006) found in Australia, the risk of death due to unintentional injury was between 2 and 15 times greater for stepchildren than for children in complete biological families. Drowning increased this effect of endangerment dramatically. Furthermore, fatalities of children who lived with zero biological relatives were present in every fatality category (violence-related fatalities, drowning, and all unintentional fatalities).

Conclusion

While the motive may vary, it seems as though sharing genetic material with the victim influences the method of killing – even in death the profound impact of the relationship is maintained. The genetic parents act quickly and choose a method that is perceived to be painless. Stepparents, lacking in genetic kinship, utilize methods that are protracted and painful. Devastatingly, children living with unrelated adults are put at an increased risk of suffering fatal harm. While intentional harm from a gun or a fist is an obvious method of filicide, patterns in unintentional fatality from accidents pose a striking resemblance to intentional methods of filicide.

Synonyms

Human leukocyte antigen (HLA) system; Major
histocompatibility complex (MHC)

Definition

The *Major Histocompatibility Complex* (MHC) refers to a large, highly dense genomic region found in most vertebrates which encodes proteins that display both self- and non-self antigens to white blood cells called T cells that can eliminate pathogens or malfunctioning cells. In humans, the MHC is also called the Human Leukocyte Antigen (HLA) system. MHC Compatibility refers to the role of the MHC in mate selection.

Introduction

Since the debut of major histocompatibility complex- (MHC) dependent mate preferences in mice in 1976 (Yamazaki et al.), a number of studies have been conducted to determine the role of MHC across species, identify mechanisms of MHC identification, and distinguish among hypotheses about the adaptive significance of having this ability. Three main hypotheses have been suggested (discussed in Penn and Potts 1999): first, that dissortative mating on MHC genotypes produces MHC-heterozygous offspring, which enhances immunocompetence (i.e., heterozygote

advantage hypothesis); second, that a preference to mate with MHC-dissimilar individuals enables the host to be a “moving target” in a coevolutionary arms race with parasites (i.e., frequency-dependent selection hypothesis, or Red Queen hypothesis); and finally, as a mechanism to avoid inbreeding and to identify kin.

Innate and Adaptive Immune System Responses

There are several lines of defense in the immune system; for example, physical barriers such as the skin obstruct the entry of bacteria and viruses from entering the body (Janeway et al. 2001). Once a pathogen has passed this initial barrier, the innate immune system responds immediately (although non-specifically to the particular pathogen). The third layer of defense, the adaptive immune system, is activated if a pathogen survives the innate immune response. This adaptive system has the unique property of antigen recognition and memory, such that the response is improved after the initial introduction of the pathogen. As a result, the adaptive immune system is able to respond more quickly and with a specified target if the pathogen is encountered again.

Both the innate and adaptive immune responses require the ability to distinguish between self- and non-self molecules (Janeway et al. 2001). *Non-self molecules* refer to peptide fragments of invading organisms, such as bacteria, viruses, or pollen. *Self-molecules* refer to peptide fragments originating from a protein created by the organism. Antigens (short for antibody generators) are molecules that bind to immune receptors, eliciting an immune response in the case of non-self molecules. MHC genes play an integral role in self- and non-self distinction. This large, highly dense genomic region is found in most vertebrates; its role in the immune system cannot be understated. The MHC encodes proteins that display both self- and non-self antigens to white blood cells called T cells that can eliminate pathogens or malfunctioning cells. T cells

recognize non-self antigens only after they have been presented by an MHC molecule.

In humans, the MHC goes by a different name: the human leukocyte antigen (HLA) system (MHC and HLA will be used interchangeably throughout this chapter when referring to human research). Most research on human MHC-dependent behaviors assay class I and/or class II molecules. Class I molecules include HLA-A, -B, and -C; these are found on all nucleated cells in the human body and present endogenous peptides (e.g., viral proteins) from inside the cell to cytotoxic T cells. Class II molecules, which include HLA-DR, -DP, and -DQ, present exogenous (e.g., fragments of bacteria or viruses) antigens outside of the cell post-phagocytosis to helper T cells that then activate a B cell immune response (Janeway et al. 2001).

Evolutionary Origins of the MHC

Beck and Trowsdale (2000) review evidence that indicates an origin of the locus predating the adaptive immune system. In fact, several MHC genes occur in the same order on the chromosomes of invertebrates such as *Drosophila melanogaster* and *Caenorhabditis elegans*. The class III region of the MHC appears to be the oldest, based on the conservation of a class III gene in yeasts. Both class I and class II regions seem to have evolved by multiple duplications. For example, HLA-DP and HLA-C show evidence of recent duplications from shared ancestral sequences.

MHC-Dependent Mating

Yamazaki et al. (1976) was among the first to identify MHC-dependent mate preferences. This study was conducted using genetically identical mice except in the MHC region and showed that the mice preferred MHC-dissimilar conspecifics as mates. The preference for dissimilarity was subsequently shown in several other species, such as salmon, sticklebacks, and humans (reviewed in Potts 2002).

Several studies were reviewed in Penn and Potts (1999; see also Havlicek and Roberts 2009) that seemed to provide general support for MHC-dependent mate preferences. Egid and

Brown (1989) showed that female mice preferred MHC-dissimilar mates when they were in estrus, providing support for an adaptive function of this ability. Mating with dissimilar individuals results in offspring heterozygosity, which may provide a selective advantage. For example, when MHC heterozygote mice were infected with HIV, they progressed more slowly to AIDS than homozygotes (Carrington et al. 1999). Similarly, the proportion of MHC heterozygote progeny increased when an epidemic struck a mice colony (Wedekind et al. 1996). A separate study showed that when mice were administered a viral vaccine, virus escape mutants emerged more easily in MHC homozygous mice than in heterozygous mice (Weidt et al. 1995).

At least in mice, MHC-based mate preference may develop postnatally (the case may be different in humans as will be discussed later). Yamazaki et al. (1988) showed that it is mediated by olfactory experience; moreover, mice tended to avoid maternally derived matching MHC haplotypes. Providing further evidence for postnatal imprinting, cross-fostered mice preferred mates dissimilar from the foster family even if it meant mating with more MHC-similar conspecifics (Beauchamp et al. 1988). Interestingly, MHC odor identity may be encoded spatially (Schaefer et al. 2002). This study showed that mice are able to distinguish one another based on a suite of alleles. In addition to identifying individual body scents based on genetic differences in all class I genes, mice can also identify individuals based on a single class I gene alone. Moreover, neural activation patterns in the main olfactory bulb are different and unique for odors from genetically different mice.

An important limitation of the aforementioned studies using mice models is that mice are not tested in their natural environment (Petrinovich 1979), which discounts the role of systemic processes and limits the generalizability of the findings. An elegant solution to this problem comes from research on three-spined sticklebacks (Eizaguirre et al. 2009). This study measured the reproductive success of sticklebacks that were placed in seminatural enclosures located in their natural breeding areas. As a result, these fish were

continuously exposed to parasites that lived in their natural ecology but were isolated from the risk of predators. Eizaguirre et al. (2009) genotyped nearly 4000 eggs using nine microsatellites to determine parenthood and to infer female mate choice. The results of this study showed that females tended to prefer males with an intermediate MHC diversity (i.e., not too similar, but not too dissimilar either). Moreover, in support of a preference for “good genes,” females also tended to prefer males with an MHC haplotype that resulted in stronger immunity against a common parasite. As a result, these males enjoyed more reproductive success than males without this haplotype. This finding seems to indicate that the female mate choice “favored locally adapted genes against the most prevalent pathogens” (p. 3317).

Human Evidence

Several studies have examined the role of the MHC in mating using the so-called T-shirt paradigm because human chemosensory communication is thought to occur via the apocrine glands in the skin, which do not significantly develop in adults until puberty. Apocrine glands are associated with hairs and are concentrated in the axillary organ, or armpits, but are also found around the navel, chest, breasts, areola, and genitals. Mechanisms for MHC identification and discrimination by the main olfactory system (Pause et al. 1996; Schaefer et al. 2001) may lie in its genetic influence of microbial flora (Singh et al. 1990) and concentrations of volatile acids (Singer et al. 1997). Axillary sweat has more volatile organic compounds than saliva or urine (Penn et al. 2007) and thus may be an important medium for MHC information transmission in humans. Importantly, Penn et al. (2007) found “odor fingerprints,” such that humans can distinguish the scent of different individuals. However, in monozygotic twins (but not dizygotic twins), odors are perceived as coming from the same individual (Roberts et al. 2005).

Wedekind et al. (1995) were among the first researchers to study human MHC-dependent body odor preferences, showing that naturally cycling females rated MHC dissimilar odors as more pleasant than MHC similar odors. The

women also indicated that MHC dissimilar odors reminded them of a current or past mate. In a follow-up study, the same authors examined whether MHC-dependent mate preferences aim for a specific MHC haplotype or just general dissimilarity from one’s own MHC haplotype (Wedekind and Furi 1997). Using the same design as the 1995 study, participants who were typed at three HLA loci were asked to rate previously worn t-shirts (the wearers of which were also typed for the same three HLA loci) on pleasantness and intensity, guess the gender of the t-shirt wearer, and to write memories for associations to relatives or mates. While the raters were unable to correctly guess the gender of all of the t-shirt wearers (although females tended to be better at guessing), memory associations for past or current mates were associated with fewer shared MHC alleles. In both the 1995 and 1997 studies, naturally cycling women preferred MHC-dissimilar odors as expected. Interestingly, however, women using contraceptives tended to prefer MHC-similar odors. The authors interpreted the latter finding as a reflection of how hormonal contraceptives work: by simulating pregnancy. Thus, women whose bodies “think” they are pregnant tend to prefer similar odors because they indicate kinship. Who better to associate with than kin if a woman is pregnant?

The role of oral contraceptives in MHC preference was explored more fully in a longitudinal study where women were tested before and after initiating birth control use (Roberts et al. 2008). Using a within subjects design, these authors assessed female odor preferences using t-shirts twice over a 3-month period. For the first assessment period, which occurred between days 10 and 14 of the ovulatory cycle (corresponding to the days of highest fertility and ovulation), all of the women were naturally cycling (i.e., not using hormonal contraceptives). The second assessment period occurred approximately 3 months later during the same window; however, about half of the women initiated the use of hormonal contraceptives in the interim while half remained naturally cycling. During each assessment, the women were presented with three MHC similar and three MHC dissimilar male odors and were asked to rate

them on pleasantness, intensity, and desirability (as a long-term partner), and to write any odor associations with current or past partners or with relatives.

While the results failed to show a significant effect of MHC dissimilarity in either session one or session two, nor did they show an effect of male heterozygosity on any of the three characteristics measured, there was an interesting effect with regard to the initiation of birth control use. The data showed a decreasing preference for dissimilarity across the two sessions for the pill-using group. In other words, after taking birth control, women tended to prefer MHC dissimilar mates *less*, thus showing a direct effect of contraceptives on MHC preference.

There is reason for concern for this shift in preference. For example, there is evidence for spontaneous abortion of MHC-similar pregnancies (Ober 1992), which indicates a mechanism of postcopulatory mate choice. On the other hand, Hedrick (1992) showed that MHC homozygous abortions did not occur at higher than chance rates and concluded that the deficiency of homozygotes in the study sample provides evidence for dissimilar mate selection. Mating with MHC-similar individuals may also result in longer interbirth intervals (Roberts et al. 2008), and homozygosity may be undesirable because it handicaps the organism's ability to thwart pathogens (Carrington et al. 1999; Weidt et al. 1995).

While MHC homozygosity may be undesirable for the aforementioned reasons, too much heterozygosity may be undesirable as well (Eizaguirre et al. 2009; Penn et al. 2007; Roberts 2009). An associated cost of having too diverse of an MHC may lead to the preference for an intermediate preference found in several studies (Eizaguirre et al. 2009; see also Roberts 2009 for a review). In addition to being costly, MHC dissimilarity may be in competition with other desirable traits, such as good genes.

Jacob et al. (2002) conducted a study to determine whether HLA discrimination is based on exposure to family members during development or on inherited HLA alleles. As previously noted, studies in mice have shown a role for postnatal imprinting (Beauchamp et al. 1988; Yamazaki

et al. 1988), but this possibility had not yet been examined in humans. The results of Jacobs et al. showed that odor preference was related to HLA similarity, such that women tended to prefer odors of individuals who had more allele matches with themselves. These preferred HLA similar odors were also *not* rated as more familiar, as has been shown in previous studies (e.g., Wedekind and Furi 1997). The most interesting finding, however, was that the preference was based on the HLA alleles that a woman inherited from her father, but not her mother. In addition, there was a positive correlation between the number of matches to paternally inherited alleles and the rating of the odor. Furthermore, alleles that were not inherited did not influence odor preference even though the women were exposed to them during development.

The findings from Jacob et al. (2002) are complemented by a naturalistic study that measured HLA similarity in a sample of married Hutterites (Ober et al. 1997). They found that fewer married couples matched on HLA haplotypes than would be expected by chance. In those couples that did have matching HLA haplotypes, the haplotype was significantly more likely to be inherited from the father. When maternally inherited alleles were involved, however, HLA dissimilar mate preferences were found. Potts (2002) suggested that paternity uncertainty may underlie the mediation of paternal inheritance in odor preference and that imprinting on paternally inherited MHC would serve as a robust source of paternal information.

Conclusion

Numerous studies have examined the role of the MHC/HLA in human mating preferences with conflicting results. Of the 21 studies reviewed by Havlicek and Roberts (2009), five investigations of body odor preferences reported significant disassortative (i.e., preference for MHC dissimilar to oneself) effects, one intermediate dissimilarity effect, and three nonsignificant tests. Of the tests of MHC influence on mate facial preferences, three showed preferences for heterozygosity, one

for assortative mating, and four were nonsignificant. Among investigations of the role of MHC in marital choices, two reported disassortative pair-bonds, one assortative pair-bonds, and seven were nonsignificant. Thus, while extant inquiries provide some support for MHC-based mate preferences, further research is necessary to elucidate the conditions under which they produce a measurable effect on mating behavior and offspring survival.

²University of Rochester, Rochester, NY, USA

Professional Life

Michael Anthony Woodley of Menie, Yr. (Younger), is a self-described sociobiologist with interests in traditional and molecular behavioral genetics, community and theoretical evolutionary ecology, evolutionary cliodynamics, and psychometric theories of human intelligence and life history (LH) strategies.

Woodley of Menie is a Lifetime Fellow at the Center Leo Apostel for Interdisciplinary Studies, Vrije Universiteit Brussel, Brussels, Belgium.

His most notable contributions have been: (1) Cognitive Differentiation-Integration Effort Theory, which concerns the systematic attenuation of the correlations among the different components of human intelligence by slower LH speeds; (2) the Co-Occurrence Model of Secular Trends in Human Intelligence, which resolves *Cattell's paradox*, or the apparent incongruity

between the observations of persistent selection against intelligence (which is highly heritable) and rising IQ test performance over time (i.e., the Flynn effect); and (3) the Social Epistasis Amplification Model, which posits that (i) deleterious mutations have been accumulating in certain populations due to the relaxation of purifying selection over recent historical time, and (ii) some of these mutations are “spiteful,” meaning that they have the potential to reduce the fitness of organisms that do not carry them via inter-organismal gene-gene transactions, i.e., social epistasis, and thereby undermine the group-level fitness of entire populations. Since its introduction in the early 2010s, the Co-Occurrence Model in particular has inspired an increasing amount of empirical research and generated some vigorous controversy (see Sarraf 2017).

The sections below discuss a few details of Woodley of Menie's background, his history of education, and his most notable contributions to science.

Background

Michael Anthony Woodley of Menie, Yr., was born in Guildford, United Kingdom, on 16 May 1984. His father, also named Michael Woodley of Menie, is the (28th) Feudal Baron of Menie (Dewar 2001, p. 1530), and his mother is named Caroline, née Cuthbertson. His younger brother is named Anthony, an independent filmmaker, and his younger sister is named Perdita, now surnamed McShan, an Events Organizer. His father's family has its roots in the Scottish landed gentry, and he is related to the twentieth-century Scottish Industrialist William Ritchie, who co-founded the engineering firm Grant, Ritchie & Co. He is also related, through his mother, to Lauren Cuthbertson, a Principal Artist of the Royal Ballet, and to Professor Keith Cuthbertson, a Professor of Finance and Macroeconomics at the Cass Business School, City, University of London.

Woodley of Menie spent most of his childhood in a country house named The Ford, in Northern Surrey, England, which was once owned by

Steven Coleridge, the author of a book about the residence entitled *Digressions*. While living there, Woodley of Menie attended the General Gordon Memorial School, a military school founded by Queen Victoria, and graduated in 2002. Afterwards, he began his undergraduate work at Columbia University, New York, majoring in ecology, evolution, and environmental biology and completing his BS in 2007. He was then accepted into the plant sciences program at the School of Biological Sciences, Royal Holloway, University of London, which conferred his PhD in 2011. He was a 2015 Recipient of an Association for Psychological Science *Rising Star* designation for producing the best-supported model of the Flynn Effect (as evidenced by Pietschnig and Voracek 2015) based on LH theory. Most recently, he was identified as one of the top six most frequent contributors to the journal *Intelligence* (the leading journal of intelligence research; Pesta 2018) and was appointed to the editorial board of that journal in 2018.

Major Contributions

Cognitive Differentiation-Integration Effort Theory

In 2011, Woodley of Menie published a notable meta-analysis of all the data then available on the relation between the general factor of intelligence (g) and the general factor of LH strategy (K), finding no significant or substantial relation whatsoever. This meta-analysis was occasioned by and contradicted the prior predictions of human LH theorists, such as J Philippe Rushton, who argued that g and K should be positively associated at the individual-differences level – meaning that higher levels of g should go with *slower* LH speeds (i.e., higher levels of K). This prediction was reasonable given that slower LH speeds positively correlate with brain size across many nonhuman animal species (see, e.g., Rushton 2004). Nevertheless, nearly every psychometric laboratory in the world that has investigated the relationship between g and K has failed to find any substantial association between these variables at the individual-differences level in humans, consistent

with Woodley of Menie's meta-analytic finding. The Ethology and Evolutionary Psychology (*EEP*) Laboratory at the University of Arizona conducted most of this research and could find no appreciable correlation between g and K over the better part of a decade (the “naughties”). *EEP*'s meta-analysis of this research yielded a negligible, but positive and statistically significant, correlation between g and K ($\rho = 0.06$, $p < 0.05$). What Woodley of Menie did next was something that is widely recommended, although seldom practiced, within empirical science: he made a risky prediction regarding the true nature of the relationship between g and K (Woodley 2011). This prediction was called the Cognitive Differentiation-Integration Effort (*CD-IE*) hypothesis. This hypothesis proposed that higher levels of K may not greatly influence absolute levels of g , but instead attenuate the *strength* of the positive manifold of correlations among the indicators that constitute the common factor of g . To test this theory, he contacted the *EEP* laboratory that had accumulated the preponderance of the aforementioned disconfirmatory data, and shortly thereafter published four successful empirical tests that demonstrated and replicated the *CD-IE* effect (Woodley et al. 2013a). Later that year, the same team (Figueredo et al. 2013) extended this theory to apply to the strength of the positive manifold of correlations among the indicators of K , showing that higher values of K tend to decrease the loadings of that common factor among its own constituent indicators (LH traits); Spearman's Law of Diminishing Returns (*SLODR*) identifies an analogous phenomenon in the case of g . This theoretical generalization was named the *Strategic* Differentiation-Integration Effort (*SD-IE*) hypothesis, in contrast to the previously proposed *Cognitive* one. The hypothesis was immediately supported by the converging evidence of multiple successful replications, which was reported in a publication that also cross-validated *SD-IE* in several demographically heterogeneous samples (Figueredo et al. 2013).

Several years afterwards, an expanded version of the same team of *EEP* researchers cross-validated both the *CD-IE* and *SD-IE* effects cross-culturally in cross-sectional data at the

level of synchronic subnational- and national-level politics (e.g., Figueredo et al. 2016).

All of these differentiation-integration theories hold that the differentiation of these common psychometric factors constitutes an adaptive niche-splitting response to inter-individual competitive pressure, as in the *Coral Reef Model* of the evolution of individual differences in personality (Figueredo et al. 2005); further, they hold that the integration among these factors' indicators represents an adaptive response to the presence of environmental instability and unpredictability, favoring obligate generalism.

The Co-Occurrence Model of Secular Trends in Human Intelligence: General Intelligence Decline

Woodley of Menie is best known for his work on declining g in Western populations, as distinguished from secular increases in other dimensions of human intelligence (the Flynn effect); these two trends are the *explananda* of the *co-occurrence model* (see the immediately following section on “[Partitioning IQ Change](#)”). He and his colleagues have argued that the primary cause of this decline is the tendency of individuals with higher levels of g to have fewer children than their lower- g counterparts. Woodley of Menie et al. (2017a) argued that industrialization and climatic warming imposed this regime of “dysgenic” fertility (or selection) favoring lower population levels of both g and group-selected altruism in the West, in that these phenomena reduced environmental harshness; both theoretical considerations and empirical evidence support the idea that g advantages the fitness of groups and individuals in harsh environments but lowers their fitness in more benign environments, where selection pressures are reversed. This evolutionary explanation of falling population-level g is called the theory of dysgenic selection.

Woodley et al. (2013b) first documented strong evidence of declining g through examination of an apparent secular slowing of simple visual reaction times, which are moderately negatively correlated with g (faster reaction times go with higher g ; $r = -0.3$ to -0.4), in five Western populations over a span of 120 years (1884–2004).

Evidence of slowing simple reaction times prompted Woodley of Menie and his collaborators, and also prompted some separate research teams, to search for other trends indicative of longitudinal changes in population levels of g . In total, temporal trends in six individual-level indicators of g were discovered from 2013–2016, all of which suggest g -decline. Specifically, measures of working memory, color acuity, spatial-rotation ability, developmental stability, vocabulary usage, and, as already mentioned, simple (visual and auditory) reaction times have all trended in ways that evince temporal decreases in g (see Sarraf 2017 for a review). Notably, apparent declines in working memory, which Woodley of Menie and Fernandes first noted in 2015, have been corroborated through a large- N meta-analysis (139,677 participants) of performance on two working memory tests across 43 years (Wongupparaj et al. 2017). Additionally, per capita rates of genius-level intellects and major innovations, two *group-level* indicators of population g , fell over the course of roughly 150 years in the West, from the mid-nineteenth to early twenty-first centuries (Woodley 2012b; Woodley of Menie et al. 2017c).

These trends that evidence falling g have been termed *Woodley effects* after Woodley of Menie by Charles Murray (Sarraf 2017). Using data sourced from Britannic (mostly Anglo-American) populations, Woodley of Menie et al. (2017a) demonstrated that a representative sample of known Woodley effects load onto a chronometric latent factor, which evidently tracks population-level g over time. This factor in turn loads onto another chronometric latent factor, called the “Co-Occurrence Nexus,” and tracks temporal changes in selection for g , congruent with the theory of dysgenic selection (Woodley of Menie et al. 2017a; see also Woodley and Figueredo 2013). Consistent with these results, Woodley of Menie et al. (2018b) found that the decline in this chronometric g factor is significantly associated with reductions in the frequencies of genetic variants related to g (Kong et al. 2017 offered the strongest evidence to date that such gene frequencies are in decline, and that this decline is due to dysgenic selection).

Michael A. Woodley of Menie, Yr., Fig. 1 Decline in chronometric g factor (the Woodley effect) from 1876 to 2008 in Britannic populations

Figure 1 shows the decrease in the chronometric g factor in Britannic populations (data sourced from Woodley of Menie et al. 2017a). Woodley of Menie et al. (2017a) estimated that this decline in g probably constitutes a loss of 1.21 points per decade in Britannic groups (p. 91), which is severe.

The Co-Occurrence Model of Secular Trends in Human Intelligence: Partitioning IQ Change

Combining the insights produced by the differentiation-integration models for both g and K with those provided by the co-occurrence model of intelligence decline, Woodley of Menie (Woodley, 2012a, b) set about accounting for the Flynn effect in terms of which IQ components might be increasing and which others decreasing. His finer-grained analyses suggested that the observed decreases in g were occurring concomitantly with secular *increases* in s , the IQ components associated with more specialized mental abilities rather than general intelligence. The aggregate rise in total IQ scores observed was thus the product of the increases in s masking the concurrent decreases in g when researchers

do not adequately partition these variance components. For example, this phenomenon is illustrated by the opposing secular trends in *backwards* digit span (a measure of working memory, an ability that exhibits high affinity for g) and *forwards* digit span (a measure of short-term memory, an ability that exhibits high affinity for s), which further evidence the validity of the co-occurrence model (Wongupparaj et al. 2017; Woodley of Menie and Fernandes 2015).

This line of investigation led to the publication of two monographs testing the co-occurrence model and framing it within the evolutionary-biological theory of multilevel selection (MLS). The first of these two monographs (Woodley and Figueredo 2013) examines the historical variability in heritable general intelligence over the period spanning most of the nineteenth and twentieth centuries, such as by tracking the effects of population aggregates of both g and s upon the rates of *eminence* (that is, measures of the prevalence of genius-level intellects) and socially significant *macro-innovations* within the aggregate Britannic population. The main conclusion of the structural equation model comparison performed was that

only *g*, and not *s*, had statistically significant effects upon *eminence* and *macro-innovations*. The second of the recent monographs (Woodley of Menie et al. 2017a) presented a more detailed biohistory of the modern era from the seventeenth century to the present time. This second monograph explicitly tested the theory of *MLS* proposed in the first as a hypothesized set of opposing causal influences upon the balance of *g* and *s* within the aggregate Britannic population. Historical trends indicated that higher intensities of group-level selection (as measured by a theoretically specified set of convergent indicators of between-groups competition) select for higher aggregate levels of *g*, and that higher intensities of individual-level selection (as measured mostly by historical periods of low climatic harshness and instability) promote higher aggregate levels of *s*. Together, these two monographs offer compelling evidence in favor of the co-occurrence model and the hypothesized evolutionary dynamics presumably underlying a wide array of observed phenomena.

The Social Epistasis Amplification Model

The social epistasis amplification model (SEAM) is based on two ideas. The first is that deleterious mutations accumulate in industrializing and industrialized populations, because the high standards of living that industrialization enables reduce the fitness costs of harboring such mutations (relative to their fitness costs under pre-industrial existential conditions). The second is that inter-organismal cross-genomic transactions may occur among the members of populations of some social species – a phenomenon called social epistasis – such that the genotype of one organism can influence the relationship between *another* organism's genotype and phenotype (for example, by epigenetically modifying patterns of gene expression). Given these premises, and assuming that social epistasis occurs in humans, the SEAM posits that the effects of deleterious mutations in carrier humans can be externalized onto non-carriers via social epistasis, and thus that the fitness costs of these mutations can be amplified. In this model, mutations with deleterious effects on both carriers and non-carriers have been termed

“spiteful mutations” (Woodley of Menie et al. 2017c); the SEAM further asserts that the accumulation of spiteful mutations in populations that have industrialized (or are industrializing) has led to an amplification of fitness costs over time. The potential existence of such intensifying fitness costs suggests the possibility that the socially selected extended phenotypes of entire industrialized/industrializing human populations and (consequently) their group-level fitness have been degraded. Indeed, the SEAM was originally developed partly as an explanation of the sharp decline in the fertility rates (a group-level fitness measure) of Western populations over multiple recent decades (Woodley of Menie et al. 2017c).

One of the more provocative hypotheses derived from the SEAM is that socially radical or antiestablishmentarian beliefs, ideologies, and behavioral patterns may at least in part be consequences of the action of deleterious mutations in psychological development that are disruptive of evolved social adaptations; furthermore, it has been argued that these beliefs, ideologies, and behavioral patterns may have proliferated quickly by way of social epistasis, with the effect of lowering the aggregate and relative fitness of groups (Sarraf and Woodley of Menie 2017; Woodley of Menie et al. 2017c). Support for this hypothesis comes from the fact that certain anti-establishmentarian beliefs and ideologies are negatively correlated with fitness both within and across populations (Woodley of Menie et al. 2017c). There is also more direct evidence of a positive association between irreligiosity (an anti-establishmentarian behavioral disposition) and burdens of deleterious mutations. The strongest evidence for this association to date comes from a sequential canonical cascade analysis of the US population, which found that relaxed opportunity for selection positively predicts a factor hypothesized to track mutation load (comprised of converging measures of developmental instability), which in turn positively predicts a “social epistasis” factor (comprised of converging measures of maladaptive social behavior, including irreligiosity operationalized as church absenteeism). This social epistasis factor finally negatively predicts a group-level fitness factor, meaning that

higher social epistasis goes with lower group-level fitness, as the SEAM predicts (Sarraf et al. 2019).

Despite these promising results, the SEAM as applied to humans still lacks fully satisfactory empirical support. Highly compelling evidence for the model has been found in experimental work on laboratory mice, however. Most saliently, Kalbassi et al. (2017) discovered that mice without the gene *Nlgn3* cause mice housed with them that have *Nlgn3* to adopt autistic-like behaviors (deletion of *Nlgn3* is associated with autistic-like behaviors in mice). Sarraf and Woodley of Menie (2017) contended that these findings potentially indicate that social epistasis occurs between mice with and without deletion of *Nlgn3* allowing for the phenocopying of these autistic-like traits therefore, they argued that Kalbassi et al.'s (2017) results may be best explained through the SEAM. Subsequently, Woodley of Menie and Sarraf began working with the team behind the Kalbassi et al. paper. Their first collaborative effort sought to uncover the mechanism(s) by which the apparent *Nlgn3*-deletion-based social epistasis occurs. An experiment investigating this matter determined that mice without *Nlgn3* excrete a urinary pheromone called Darcin, exposure to which “deleteriously modif[ies] the social behavior” of mice with *Nlgn3* (Bachmann et al. 2018).

Controversies

Controversies have attended some of Woodley of Menie's work. Three of these in particular are of note: (1) a number of academics critiqued his and certain colleagues' research on slowing simple reaction times as indicators of declining *g*; (2) a prominent endocrinologist argued that his dysgenic theory of falling *g* is problematic and that an alternative theory invoking neurotoxic pollution to explain this decline is more scientifically sound; and (3) a variety of media outlets condemned the London Conference on Intelligence, for which Woodley of Menie served as secretary in 4 of the 6 years it has been held, for what they claimed were moral and scientific reasons.

Reaction Times

The reaction times controversy began with Woodley et al.'s (2013b) previously discussed meta-analytic finding of slowing simple visual reaction times from 1884 to 2004 in five Western populations. That meta-analysis received one of the largest numbers of critical commentaries ever directed at a single publication in the journal *Intelligence*. In total, five replies were written by six academics: James Flynn, Ted Nettelbeck, Irwin Silverman, Yulia Dodonova and Yury Dodonov, and Scott Parker. David Woods led one other critique that appeared in a different journal, *Frontiers in Human Neuroscience*. (See Sarraf 2017, for a more involved treatment of these papers.)

The criticisms offered in these papers are too numerous to be detailed in full here, but perhaps the most significant alleged problem raised, and the one mentioned the most frequently, was that methods for gathering reaction times data have varied substantially across samples. This potential problem introduced the possibility that apparent declines in simple reaction speed were not substantive, but rather merely artifacts of methods variance. Nevertheless, Woodley of Menie and colleagues replied that profound slowing of simple reaction times still emerged from relevant data even after applying generous adjustments for methods variance (Woodley et al. 2014b; Woodley of Menie et al. 2015a, b). More importantly, studies of modern cohorts using invariant methods to measure simple auditory (Madison et al. 2016) and visual (Woodley et al. 2014a) reaction times also found significant temporal slowing. These results, which have so far received no academic challenges, leave little doubt that the simple reaction times of at least some Western populations have slowed considerably over time.

Neurotoxic Pollution Versus Dysgenic Selection

As already indicated, Woodley of Menie has perhaps done more than any other scientist to revive the theory of dysgenic selection. But competing theories have been forwarded to explain the apparent long-term diminishment of human cognitive ability. One example comes from Demeneix's (2017) book, *Toxic Cocktail*, which

maintains that increasing human exposure to endocrine-disrupting neurotoxic pollution explains at least some significant portion of the apparent decline in intelligence (it is not clear whether Demeneix believes that this decline applies only to *g*). While recognizing that neurotoxic and dysgenic theories need not be mutually exclusive, Demeneix has been clearly skeptical about the latter. Referring specifically to the study of Woodley et al. (2013b), Demeneix (2017) asserts that their dysgenic theory exhibits objectionable “biological determinism and genetic determinism” (p. 87). Further, she argues that their work fails to take seriously the possibility that neurotoxic effects have some role in evident diminutions of intelligence. Demeneix’s (2017) criticisms are purely qualitative, however, making their commensurability with the prior quantitative findings unclear.

In light of these criticisms, and of the lack of adequate assessments of neurotoxic theories of *g* decline, Woodley of Menie et al. (2018b) developed a statistical model to test the dysgenic selection and neurotoxic pollution theories. This model involved the use of composite measures of changes in population-level gene frequencies related to *g* and neurotoxic pollution over time and indicated which of these measures better accounted for trends in a third temporal composite measure, of population-level *g*, statistically controlled for the effect of time. Decreasing *g*-related gene frequencies significantly predicted declines in *g*, whereas trends in neurotoxic pollution were not significantly related to these declines, providing strong evidence in favor of the dysgenic theory and against the neurotoxic pollution theory (Woodley of Menie et al. 2018b).

The London Conference on Intelligence

The London Conference on Intelligence (LCI) is an academic meeting, attended by invitation, devoted to discussion of psychometrics and differential psychology. It has been held for six consecutive years (2014–2019); Woodley of Menie served as secretary for the conference for the first four meetings.

On the 10th of January 2018, an article appeared in *London Student*, a student newspaper of

University College London (where LCI was held from 2015–2017), alleging that LCI had the purpose of promoting racist and eugenicist ideas. Similar claims were published in a variety of other media outlets (see Woodley of Menie et al. 2018a, for discussion of a number of these pieces). The general theme of these articles is that the scientific work presented at LCI was not only morally abhorrent but also represented discredited “pseudoscience.”

In order to refute these claims, Woodley of Menie and a number of colleagues (2018a), all of whom had attended LCI, published a piece in the journal *Intelligence*. This article provides evidence that, contrary to media allegations, the research associated with LCI was mainstream in form and content among experts on intelligence research and had been conducted by persons of diverse national backgrounds. Further to this point, it demonstrates, via scientometric analysis that papers presented at LCI were associated with mainstream scientific publications about as strongly as was research typically presented at biomedical science conferences. Finally, the article offered an analysis of temporal trends in word usage, which provides evidence that past efforts (stemming mostly from the political left) to stop research on “distasteful” psychological issues (for example, group differences in intelligence) have had a chilling effect on such research, despite its manifest scientific credibility. Woodley of Menie and colleagues termed this social psychological phenomenon the *Gould effect*, after the Marxist evolutionary biologist Stephen J Gould. The basic thrust of Woodley of Menie and colleagues’ (2018a) response to media critics was that the work featured at LCI had not been outside of the relevant mainstream of science; instead, it was the critics of LCI who had approached scientific matters in a decidedly politicized and unscientific way.

Definition

Michael Tomasello has pioneered theoretical and empirical work on the evolution of uniquely human cognition and behavior.

Introduction

Michael Tomasello has developed novel methodological and theoretical tools within the field of evolutionary psychology and, using these, has contributed significantly to the collective effort to understand what it means to be human. A thorough understanding of any object of study requires points of comparison. Nonhuman great apes (henceforth apes) serve as particularly salient subjects for comparative research due to their close phylogenetic tie to our species. Features held in common may be argued to have been present in our last common ancestor (LCA), while differences suggest derived traits in a particular lineage. Tomasello has innovatively implemented controlled comparative experiments

using both apes – chimpanzees in particular – and human children as subjects. In doing so, and by keeping the experimental design as similar as possible across species, Tomasello has been able to illuminate aspects of ape and human psychology in the realms of both physical and social cognition, allowing for the piecing together of the evolutionary trajectory of these traits. In addition, Tomasello has studied children of different ages to further reveal ontogenetic patterns in the development of these cognitive abilities. While it is relatively straightforward to point to contrasts at the species level such as language, institutions, and religious beliefs, it is more challenging to capture the subtle differences in psychology on an individual level which in turn account for the more surface-level species differences. Tomasello's controlled experimental methodology allows researchers to focus on even these more fine differences. The resulting body of work has provided robust support for Tomasello's theory of shared intentionality which posits that apes operate from an individual, or "I," perspective, while humans possess a suite of socio-cognitive skills that allow them to put their heads together in acts of shared intentionality resting on a "we" perspective. It is this ability which allows humans to create the shared realities that give life its distinct character.

This chapter will first provide an overview of the methodological approach pioneered by Michael Tomasello – the comparative approach – through discussion of a representative study. The chapter will then continue in a second section to explore the conceptual foundation of Tomasello's shared intentionality theory and the socio-ecological circumstances that likely played a role in its evolutionary emergence. A third section will offer a concrete example of how shared intentionality transformed ancestral cognitive and social skills used in communication into their uniquely human form.

The Comparative Approach

One overarching question is whether human cognition is more complex than ape cognition across

the board or whether it is characterized by a more targeted species-unique factor. The cultural intelligence hypothesis, propagated by Tomasello and colleagues in a series of influential books and papers, proposes that humans possess a set of species-specific socio-cognitive skills that allow them to participate and exchange information in cultural groups (Tomasello 1999a, b; Tomasello et al. 1993). As the key to isolating differences between apes and children is conducting systematic comparative studies, Michael Tomasello, Esther Herrmann, and colleagues designed a controlled experiment that tested the hypothesis that humans have evolved specialized social cognition skills (Herrmann et al. 2007). In this landmark study, they administered the same comprehensive battery of cognitive tests to 105 young human children, 106 chimpanzees, and 32 orangutans. The three species were exposed to 16 nonverbal problem-solving tasks aimed at measuring skills and motivation related to physical and social cognition. Tasks measuring species' grasp of the physical world measured subjects' understanding of such concepts as space, quantity, tools, and causality. Tasks measuring cognitive abilities in the social world focused on subjects' tendency to imitate others' solutions to problems, subjects' ability to communicate nonverbally, and subjects' understanding of another individual's intentions. If it were simply general intelligence that differentiates human cognition from ape cognition, then one would expect human children to outcompete their primate relatives on tasks relating to physical cognition and on tasks relating to social cognition. If, on the other hand, the cultural intelligence hypothesis holds true and human cognition is marked by unique socio-cognitive abilities, then human children in this study should only differ from the other two primate species on tests relating to social intelligence. Results of this extensive test battery support the cultural intelligence hypothesis and show that the cognitive skills of human children are very similar to those of their primate relatives in the domain of physical cognition, but differ when it comes to navigating the social world. As the cultural intelligence hypothesis argues, young children seem to possess a unique adaptation for social cognition, allowing

them to interact with, learn from, and communicate with others in ways that other great apes do not. These early developing social skills allow human children to engage in the human cultural world which includes learning from others through language, instruction, and other educational tools.

This large-scale test battery not only provides evidence of uniquely human forms of cognition but also testifies to the power of systematic comparisons between human children and great apes in answering questions about species-specific cognitive adaptations.

Shared Intentionality Theory

The test battery's confirmation that humans possess species-unique cognitive abilities in the social realm provides a firm foundation for Tomasello's shared intentionality theory. Tomasello's theory not only recognizes that apes operate from an individual perspective, while humans regularly engage a collective perspective but also asks: How did humans evolve these novel forms of social cognition and become the "ultra cooperative" species that we are today? Which set of species-specific adaptive pressures likely facilitated the emergence of human social skills? One of the most significant achievements of shared intentionality theory is its effort to build a comprehensive understanding of the evolutionary development of human socio-cognitive skills from our divergence from the last common ancestor of apes and humans all the way to our current elaborate forms of social life, including conventionalized forms of interaction (Tomasello 2014). Shared intentionality theory argues that human socio-cognitive evolution over the last 6 million years took place in two key steps (Tomasello et al. 2012). Each of these evolutionary steps involves a new form of social engagement. The first step describes the transition from the individual intentionality of our primate ancestors to the joint intentionality of early humans which arose in the context of small-scale collaborative foraging. The second step focuses on the extension of joint intentionality to collective

intentionality spurred by large-scale forms of collaborative activity, brought about by growing populations and increasing levels of intergroup competition. Shared intentionality theory provides an account of the evolution and ontogeny of the human ability to form a shared agent – a “we” with others – comprising shared goals and intentions, as well as shared attention and knowledge. Shared intentionality theory also provides an account of the socio-ecological challenges that led humans to first collaborate dyadically in acts of joint intentionality and, later, as a group with individuals sharing cultural ties in acts of collective intentionality.

The central adaptive driving force of the first step in this transition was ecological change resulting in increased resource competition between terrestrial primate species and an incentive for early *Homo* to exploit a new niche. After an intermediary stage of scavenging of large carcasses, as suggested by paleoanthropological evidence, this new niche consisted of collaborative hunting of large game. Whereas earlier humans had, like modern-day chimpanzees, likely procured the majority of their food solitarily, members of the species *Homo heidelbergensis* were increasingly forced to depend on one another in their daily foraging: they became obligate collaborative foragers (Tomasello 2014, 2016; Tomasello et al. 2012). This new form of interdependence created two especially pressing challenges. The first challenge consisted of novel pressures of social selection, including partner choice and partner recruitment. Once early humans were dependent on their collaborative partners and choosing the wrong partner meant less food, individuals had to evolve novel ways of reliably interacting with competent and trustworthy partners, i.e., they had to engage in partner choice. Partner choice stabilizes cooperation by allowing cooperators to selectively interact with other cooperators and to exclude cheaters, free riders, and bullies. However, selecting those individuals with stable behavioral dispositions who are both trustworthy and competent in collaborative interactions is not quite enough. Additionally, individuals have to make sure that they are also picked as partners, i.e., they have to engage in

partner recruitment. The prevalence of picky partners in combination with dependence on those partners meant that early humans inhabited a social ecology in which they had to worry about evaluation by others and so they started to manage the impressions they made. Early humans thus had to socially regulate their behaviors in ways other great apes do not so as to align their actions with the expectations of their collaborative partners (Engelmann et al. 2012). Partner recruitment stabilizes cooperation by providing agents with extra motivation to act cooperatively as they must ensure they are chosen for the next collaborative hunt.

The second way in which interdependence in food acquisition created novel selection pressures was the necessity of developing the skills and motivations required for successful joint collaboration and a shift in the conceptualization of dyadic collaboration (Tomasello et al. 2005). Joint agency takes place when two individuals collaborate and relate to one another dyadically and second personally in face-to-face interactions. Joint collaborative activity consists of four elements: joint goals, joint attention, individual roles, and individual perspectives (Tomasello 2014). The emergent dual-level structure of joint collaborative activity is thus characterized by simultaneous jointness (on the levels of goal and attention) and individuality (on the levels of roles and perspectives). Agents form a joint goal, that is, the joint intention to capture the prey together (anchored in common ground). To achieve this goal, individuals assume different but complementary roles, adjusting their respective sub-plans so as to most effectively pursue their joint goal. Individuals engaged in a joint collaborative activity naturally attend together to incidents and objects that are relevant to their joint goals. Joint attention creates common conceptual ground and shared realities with their collaborative partners. In much the same way as joint goals and individual roles are characterized by connection and individuality, joint attention is complemented by the agents' individual perspectives. Indeed, the notion of perspective only gains relevance in the context of an object of joint attention on which two individuals have different perspectives.

The evolutionary beginning of human uniqueness may well rest in the cognitive representation consisting of a dual-level structure of jointness and individuality, as depicted in Fig. 1. The cognitive, social, and motivational consequences of this dyadic evolutionary revolution can hardly be overstated. Some of its effects on human behavior and cognition will be reviewed in section “A Case Study.”

This dyadic, second-personal, and face-to-face form of collaborative activity was perfectly adaptive as long as humans lived in small groups with an easily manageable number of potential partners and rarely encountered other groups. According to shared intentionality theory, this system was destabilized by two demographic factors (Tomasello 2016). The first was increased competition, direct or indirect, with other groups of early humans which forced dyadic cooperation to be scaled up to collaborative activities by the whole group. If groups failed to turn their dyadic undertakings into full-blown collaborative activities on the level of the whole group, they were bound to be outcompeted by more tightly knit social groups. The second factor destabilizing humans’ early forms of joint collaborative activity was increasing population size. As groups became larger and larger, they tended to split into smaller groupings, with a number of different groups together forming a single culture. As a result, individuals did not face a manageable pool of familiar cooperation partners (as in step 1), but were increasingly forced to collaborate with relative strangers who they had to reliably recognize as members of their group. This challenge was solved by developing various markers of group

identity, allowing agents to collaborate selectively with those individuals that possessed the same skills and values as themselves and therefore likely made for trustworthy and competent collaborative partners.

The second step in shared intentionality theory, from joint to collective intentionality, is hypothesized to have occurred some 150,000 years ago, with the emergence of *Homo sapiens sapiens* (Tomasello 2014, 2016). The interdependence of You and I as part of the same collaborative dyad in the context of obligate collaborative foraging grew into interdependence at the level of the cultural group as a whole. This new form of reliance again created novel adaptive challenges relating to social selection and the ways in which collaborative activities were conceptualized. Most importantly, individuals now not only engaged with one another dyadically but started to view group life itself as one big collaborative activity. They evolved a novel psychological attitude of group-mindedness, consisting not only of skills and motivations for joint intentionality with other individuals, but for collective intentionality with their whole group. Social selection in such large groups required new forces to counter the powerful temptations to free ride under these novel conditions. The basic problem was twofold: in large-scale cooperative activities, each individual was needed less for collaboration to be successful (in comparison to the dyadic situation of step 1) and reputational information was less easy to come by – cheaters and free riders could more easily submerge into anonymity. One solution to this problem was the development of social norms – mutual expectations in common ground –

Michael Tomasello,
Fig. 1 The dual-level
structure of joint
collaborative activity

that specify how individuals are to behave in situations that typically involve non-converging interests. In essence, social norms are conventionalizations of the specific and locally restricted acts of partner choice and judgment of step 1. While failing to act cooperatively at step 1 invited reproach and punishment from my collaborative partner only, free-riding behavior in step 2 is met with protest by my entire group. Due to the generality of social norms, victims can (more or less) easily recruit assistance against cheaters and punishment is in effect not only carried out by the individual but by the whole group. Cheaters not only fail to live up to specific commitments shared by a collaborating dyad but to standards that are endorsed and enforced by the entire group.

Thus, whereas humans' collaborative activities in step 1 were marked by skills and motivations for joint intentionality, human social interaction from about 150,000 years on was characterized by collective intentionality. As suggested in the discussion of social selection in step 2, collective intentionality enabled humans to create various types of conventional practices that were firmly anchored in the cultural common ground of the group. Conventional cultural practices encompass behaviors, standards, and values that all members of our "we" engage in, follow, and endorse and that we expect everyone who wants to be a member of our "we" to engage in, follow, and endorse. Whereas the second-personal common ground of step 1 was created by, and therefore dependent on, the things experienced together during joint collaborative activity, the cultural common ground of step 2 consists of things each member of a group is expected to know – even if the related experiences were not shared or experienced together.

Collective intentionality thus shows the same dual-level structure of jointness and individuality as joint collaboration. The main difference is that the jointness has been scaled up to a kind of objectivity: our shared reality is not only shared between You and I but is shared among the entire cultural group, creating a kind of collective perspective involving various ways of doing things the "right" or "wrong" way and normative judgments of what one "should" or "shouldn't" do.

A Case Study

While so far this review of shared intentionality theory has mostly highlighted the theoretical and conceptual aspects of the theory, the third and last part will briefly discuss one concrete example of shared intentionality theory, focusing on the transition from ape communication to forms of communication unique to humans. Tomasello (2008) argues that the starting point for uniquely human forms of communication is not the relatively hard-wired forms of vocal communication in great apes, but instead their flexible and intentional forms of gestural communication. The flexible nature of chimpanzees' gestures can be clearly seen in their intention movements and attention getters (Tomasello and Call 1997; Tomasello et al. 1997). Chimpanzees ritualize certain intention movements from their social interactions with others and then use these gestures to flexibly and intentionally manipulate conspecifics, for example, when young chimpanzees raise their arm to a peer and then begin play hitting as invitation to play. Chimpanzees also use a number of attention getters in order to manipulate and direct the attention of others. For example, they regularly stomp or slap the ground in order to get others to look at them. The flexibility of their gestural repertoire is clearly evident in the special gestures used when interacting with their human caregivers, such as ritualized reaching and pointing gestures. However, while the range and flexibility of great ape gestural communication is impressive, it is limited in one important regard. When apes communicate with one another or with humans, the underlying motive is always directive and geared toward self-serving ends: getting food from a human caregiver, getting others to look at them, or getting a peer to start playing (Tomasello 2008).

In step 1 of shared intentionality theory, in order to effectively coordinate joint collaborative activities, early humans required a new form of communication. Tomasello (2008) refers to this new type of communication as cooperative communication. Interdependent activities, such as obligate collaborative foraging, invite cooperative communication. If we are hunting together, it is in my interest to inform you helpfully of things that

are relevant to your role. If your spear broke, I will point out an appropriate stick that could serve as a replacement. The first and most basic forms of cooperative communication consisted of the natural gestures of pointing and pantomime long before humans developed conventional languages.

This seemingly small step, from understanding others' gestures only in directive terms to understanding them cooperatively, allowed early humans to make novel inferences in communicative interactions. Consider the following experiment: when a human experimenter hides food in one of two buckets and then points to the location of the food, apes do not reliably use this gesture to locate the reward; they pick the correct bucket only at chance levels (Tomasello 2006). To be sure, apes follow the human gesture and look at the correct bucket, but then they do not make the inference that the gesture was offered with cooperative or helpful intent. Importantly, the problem is not that apes cannot make inferences from human behavior. When apes are exposed to the same setup only within a competitive context, i.e., facing a human experimenter who competes with them for food and who extends his arm toward one of the two buckets, they know right away that this must be the correct bucket (Hare and Tomasello 2004). Apes thus reliably make competitive, but not cooperative, inferences in the context of communication. In stark contrast, when prelinguistic infants as young as 12 months – who may be considered representative of the early humans of step 1 of shared intentionality theory – are exposed to the very same experimental situation (an experimenter pointing to one of two buckets), they readily make the necessary inference and consistently pick the bucket containing the food (Behne et al. 2005).

The evolutionary proposal is thus that early humans evolved a new type of communication – cooperative communication based on prosocial motives – which first emerged in the form of pointing gestures in the context of joint collaborative activities. This not only had significant repercussions for early humans' understanding of cooperative communicative acts, but also for their own transmission of helpful information. When apes work together in experimental studies,

there is a manifest absence of any kind of intentional communication (Hirata and Fuwa 2007; Melis et al. 2009; Povinelli and O'Neill 2000). This is presumably due to the fact that ape communication is directive in nature and not geared toward cooperatively informing collaborators of things helpful to them. Prelinguistic infants again provide a clear contrast. In the context of joint collaborative activities, infants 14–18 months of age use the pointing gesture to coordinate actions with a human experimenter (Warneken et al. 2006, 2007). Even outside of such collaborative pursuits, when infants as young as 12 months observe an adult looking for an object, they spontaneously point for the adult with the simple and pure motive of providing helpful information as to the object's location (Liszkowski et al. 2006, 2008).

The communication of early humans began to veer from intentional ape communication. In a sense, however, the strength of early humans' flexible gestural communication – successful coordination of complementary roles in joint collaborative activities – was at the same time its greatest weakness. Since these early forms of communication were so heavily contingent upon the common ground established within a joint activity, they were almost totally useless when this scaffold was removed and individuals interacted with others who did not share their common ground, or when they faced completely novel situations, or when they could not engage in dyadic, face-to-face forms of communication. To successfully communicate in these situations, early humans had to conventionalize gestures and vocalizations, making the transition from joint intentionality to collective intentionality. While the communication of early humans was locally, situationally, and temporally restricted, the advent of collective linguistic conventions enabled a much more decontextualized and flexible form of communication involving not just collaborative partners but anyone from the same cultural group. While communication between early humans was based on the personal common ground they created with one another as they engaged in collaborative activities, modern humans could communicate even with individuals

they had never met before and with whom they lacked personal common ground, thanks to cultural common ground. In Clark's analysis (1996), cultural common ground refers to pieces of knowledge that all members of a group share and that they know qua membership in the group – even if that knowledge was not gained through direct experience together. Two- and three-year-old children already understand cultural common ground and use it in order to make relevant communicative inferences (Liebal et al. 2013). When children at this age meet an unknown in-group adult and they look together at two objects, a Santa Claus toy and a newly created toy, and the adult asks, “Who is that?”, children unfailingly name the newly created toy, showing a belief that everyone from their culture knows who Santa Claus is and, therefore, would not need to ask. The transformation from communication based on personal common ground in the context of joint intentional activities to communication based on cultural common ground in the context of collective intentional activities thus allowed modern humans to coordinate their actions with all members of their group, independent of whether they had interacted together before or not (for various other consequences of the change from joint to collective intentionality for the communicative abilities of modern humans, see Tomasello 2008).

Although this is only a very brief and incomplete overview of the origins of human communication (for the full version, see Tomasello 2008), it demonstrates the power of shared intentionality theory in explaining how uniquely human forms of communication likely evolved gradually and naturally from the communicative abilities used by the last common ancestor of humans and nonhuman apes.

Conclusion

Based on an extensive body of empirical studies comparing human children and great apes, Michael Tomasello's shared intentionality theory

offers an in-depth and complete psychological analysis of the evolution of uniquely human cognition and behavior. Shared intentionality theory traces the socio-ecological pressures that contributed to the human evolutionary trajectory characterized by novel dyadic and second-personal forms of social engagement based on joint intentionality and, later, by group-based and conventionalized forms of cultural interaction based on collective intentionality.

Michelle Scalise Sugiyama

Vincent Barnett
London, UK

Definition

Michelle Scalise Sugiyama is a leading evolutionary psychologist/anthropologist who has conducted research on the evolutionary function(s) of art, play, narrative, and story-telling, mainly with respects to human prehistory but also to some degree in contemporary societies. Much of her work investigates the evolutionary origins of various aesthetic, narrative and symbolic human behaviors – i.e., the natural and sexual selection pressures that led to their emergence – the role that these various artistic behaviors played in ancestral human societies, and the cognitive design features of the mind that have made them biologically possible. She has sometimes worked in collaboration with Laurence Scalise Sugiyama, and she is based in the Department of Anthropology at the University of Oregon, USA.

The entry will be divided into two main sections. The first section will simply summarize the most salient content of Sugiyama's work as it has been presented across a range of different publications, and the second section will briefly attempt to develop and extend a particular aspect of it.

Narrative

Sugiyama has conducted innovative work on the evolutionary origins and function of narrative storytelling. In this regard, she has explained that:

The antiquity of narrative is significant. It means that storytelling is a sufficiently ancient phenomenon to have evolved through the process of natural selection and that storytelling might serve an adaptive function – that is, it might have evolved in response to a problem that recurrently impinged upon human survival or reproduction throughout recent (i.e., Upper Pleistocene) human evolution. (Sugiyama 2005, 177)

According to Sugiyama, in order to construct an evolutionary aesthetics of stories, what is needed is to “reverse engineer” the urge to make and participate in such narratives. What survival advantages did narrative stories confer on their creators and on audience participants in the evolutionary past? In this regard, she has explained:

We know that storytelling is verbal and interactive: it involves an exchange between storyteller and audience. We also know that almost without exception, characters are representations of the human psyche; furthermore, characters give us special access to the human psyche that is not available to us in the real world. Finally, we know that conflict is an expression of human problems and plans for solving them, and that setting represents the specific conditions under which those plans are executed, thwarted, accomplished, or undone. The function of narrative, then, would appear to be the representation of the problems humans encounter in their lives and the constraints individuals struggle against in their efforts to solve them. (Sugiyama 2005, 186)

The fitness benefits of modeling human behavior are, according to Sugiyama, as preparation for various important survival-related tasks, such as finding food, building shelters, maintaining group cohesiveness, and so on. In addition, the ability to accurately predict the motives and behaviors of other individuals is enhanced by means of exposure to a wide range of narrative stories, and thus narrative assists individuals in expanding their knowledge of human nature (Sugiyama 1996).

Predators

In the Pleistocene era, violent threats to human life came from two main sources: attacks by animal predators (e.g., lions, tigers, bears) or by other human competitors (either in-group or out-group). Consequently, predator avoidance was a key skill that was required for survival (Barnett 2018). Sugiyama’s work promotes the idea that one important method for passing on useful information about predator attacks was through narrative storytelling.

For example, the oral retelling of “campfire” tales of predator attacks or deadly human conflicts was one effective means by which knowledge of

previous incidents could be transmitted from individual to individual and also across the generations (Sugiyama 2006, 328–329). Early forms of visual art such as cave paintings and ivory, bone and stone carvings may have served a similar function (Sugiyama 2001, 321). Related story narratives such as forager oral traditions contained information about hunting, gathering, and their associated localized dangers (Sugiyama 2010, 485).

However, the folklore and folktales of various cultures were not always presented literally or entirely naturalistically. As Sugiyama has outlined:

Folklore may also convey information metaphorically. For example, a Mataco tale about the bat-spirit informs the audience that the creature only goes out at night and that people “must be very careful not to sleep in the open; otherwise the bat will cut their heads off”. This story appears to be a reference to the menace of vampire bats . . . they are indeed known to prey on humans who sleep in the open: the bite itself is not lethal, but the infection that may spring from it can be. (Sugiyama 2006, 330)

In some areas of the world, bites from vampire bats are more prevalent than venomous snake bites (Ibid., 322). Consequently, there is a direct correspondence between the dangerous animals found in local literatures and those found in local environments (Ibid., 328). Moreover, the symbolic presentation of animal dangers with added supernatural overtones was one effective method of ensuring that such dangers were taken very seriously and received the full attention of the target audience. Often the supernatural enhancements related only to a few additional features of the creatures being portrayed, thus enabling their natural equivalents to be easily recognized (Sugiyama and Sugiyama 2011).

Supernatural creatures such as malevolent spirits, animal-human combines, cannibalistic ogres and giants, are a common feature in the folklore of foraging cultures across the planet. Sugiyama has argued that all these imaginary monsters serve the function of frightening children in order to keep them under control and away from environmental dangers, such as becoming detached from the group and finding themselves under predator attack (Sugiyama and Sugiyama 2011). For example, *Little Red Riding Hood* is a well-known example of a wolf-centered fairytale

set in a wooded location that is likely to contain dangerous wild animals (Sugiyama 2005, 186).

Cultural Variation

One of Sugiyama's most significant contributions to understanding literary universals and context-sensitivity is her work on cultural variation and its relation to universal human nature. She has explained in relation to cultural variation that:

The principle of context-sensitivity is an important stepping stone on the path to understanding cross-cultural differences in literary interpretation ... because all habitats present the same basic set of obstacles to survival and reproduction, we would expect any given literary setting to represent one or more adaptive problems ("the human condition"). However, because literary settings are representations of human habitats, and human habitats vary, we would expect local solutions to adaptive problems to vary in literature as they do in real life. On this view, then, we would expect literary art to express both human universals (e.g., adaptive problems, cognitive adaptations) and cultural variation (e.g., local solutions to adaptive problems). (Sugiyama 2010, 485)

The specific example being considered here is how the Tiv people of West Africa interpreted Shakespeare's *Hamlet*. Sugiyama showed effectively how the Tiv response to *Hamlet* resonated with very much the same universal issues that resonated with Western audiences: kinship, fratricide, revenge, justice, and madness. The small number of interpretive differences that were exhibited when comparing the Tiv and Western interpretations of *Hamlet* were explained by differences in local Tiv customs and economy compared to those of the West, not by wider differences in evolved cognitive architecture or any major distinctions of human nature (Ibid., 489).

Extension

This section will take the argument one stage further than Sugiyama by suggesting that narrative-linked cognitive architecture is, in some ways at least, *genre*-specific or *genre*-sensitive, by which is meant, focused on

assisting in solving very specific evolutionary problems, and "playing" with the particular emotions that have been evolved in association with them. Some scholars have previously considered the concept of *genre* in relation to evolutionary psychology, suggesting that there are three basic *genres*: comedy, tragedy, and satire, each of which links with a specific set of evolved emotions (Carroll 2007, 640; Carroll et al. 2010, 216).

The horror *genre* has not previously been considered in these terms, but it will be suggested here that the emotions that horror narratives are tuned to activate – fear and terror – make this *genre* conceptually prior to all other *genres* such as romance, comedy, or science fiction (Barnett 2010) and thus, it should be understood as "the primal *genre*."

Fear has recently been identified by neuroscientists as one of the four core premammalian emotional systems, and it has been hypothesized that a specific mental module or dedicated neural network has evolved to deal with associated predator avoidance issues (Carroll et al. 2010, 212). The term "the primal *genre*" is therefore appropriate because the adaptive functions of the emotions associated with the horror *genre* – fear/ensuring the survival of an individual under threat – are logically prior to all other functions of the living organism (finding a mate, successful reproduction and so on). Therefore, horror narratives have an enduring popularity in the contemporary world because their evolutionary equivalents rehearsed scenarios of extreme threat and danger that were much more prevalent amongst our evolutionary ancestors than they are today.

Moreover, the emotions of fear and terror should not be understood as corresponding with the themes of the tragedy *genre*, as some have suggested (Carroll 2007, 641), but instead they should be seen as a part of a separate *genre* which is conventionally called horror but could, more literally, be labeled as the predator-prey interaction *genre*, or a *genre* which documents the traumatic association of two separate species or two groups within a species, one of which preys on the other with deadly intent as a result of asymmetric power relations (Volterra 1931, 414).

Conclusion

In her extensive range of work, Sugiyama has pioneered the evolutionary investigation and understanding of the function of narrative storytelling by attempting to “reverse engineer” the need for such stories, especially in relation to an understanding of the function of predator/monster narratives. This entry has attempted briefly to extend Sugiyama’s analysis of the function of narrative by suggesting that the evolved cognitive architecture associated with storytelling is genre-specific and linked to particular systems of emotion, and identifying horror/terror as “the primal genre.”

Sugiyama has also demonstrated how cultural variation in the interpretation of narratives is compatible with the evolutionary psychologist’s conception of a universal human nature. Overall, Sugiyama’s work can be characterized as a valuable, empirically rich, and highly original addition to the body of work that attempts to further develop the Darwinian approach to art and literature (Carroll 2007).

Definition

The part of the ear between the eardrum and the oval window which contains the three bones (malleus, incus, stapes), the tympanic muscles (Stapedius and tensor tympani), the oval window, the round window, and the Eustachian tube.

Introduction

The middle ear has three bones that make the ossicular chain, namely, the malleus (hammer), incus (anvil), and the stapes (stirrup). These are responsible for the sound to reach the tympanic membrane. The oval window, along with the round window, work with an opposite way to each other in order to influence the perilymph of the cochlea to move in response to sound. The two tympanic muscles, Stapedius and Tensor Tympani help to protect the inner structures of the ear from

damage of high intensity and frequency sounds. Further, the round and oval window work together to transmit sound to the structures of the inner ear. The Eustachian tube is to allow mucous to flow out of the middle ear and the air (oxygen) to move into and out of it. It is also used to balance the pressure levels inside the middle ear. Furthermore, the evolutionary patterns of middle ear's ossicles are briefly discussed.

Brief Anatomy of the Middle Ear

The middle ear is a part of the ear which is filled with air and where the structures of the tympanic membrane are located. Specifically, it is comprised of the ossicles – bones of hearing – called the hammer, anvil, and stirrup, or otherwise called the malleus, incus, and stapes, respectively (Hoy 2012). The aforementioned ossicles make the ossicular chain, which are responsible of the sound energy to travel to the tympanic membrane and, ultimately, to the structures of the inner ear (Seikel et al. 2010).

Stapedius and Tensor Tympani

There are, also, two tympanic muscles connected to the ossicles called the Stapedius and the Tensor Tympani. (Seikel et al. 2010). These muscles contract when exposed to high-intensity sounds, and together they compose the middle-ear reflex arc involving the spiral ganglion neurons, the auditory nerve, cochlear nucleus, the superior olive, the facial nerve nucleus, and the facial nerve (Margolis 1993, as cited in Puria and Steele 2008).

The reflex arc can reduce sound transmission through the middle ear at higher intensity (Puria and Steele 2008). As a result, when these muscles contract, they reduce the signal strength of reaching the cochlea, thus protecting the ear from being harmed from high-intensity sounds (Seikel et al. 2010). There are also two more functions attributed to the middle-ear muscle reflex. High-intensity sounds with low frequency tend to mask mid- and high-frequency sounds because of the upward excitation patterns on the

basilar membrane. Therefore, one role of the middle ear muscles is to reduce the level of the low frequency sounds so they do not mask the higher frequency sounds on the basilar membrane (Puria and Steele 2008). The other role of the middle ear reflex is to reduce the hearing of self-generated sounds such as sound made by speech, yawning, sneezing, and chewing (Puria and Steele 2008).

The Stapedius originates from the posterior wall of the middle ear space of the temporal bone. Its function is to rotate the footplate of the stapes posteriorly, thus thickening the ossicular chain. The Tensor Tympani is originated from the cartilaginous portion of the Eustachian tube and the greater wing of the sphenoid. Its function is to pull the malleus anteromedially and reduce the movement of the Tympanic Membrane by placing indirect tension on it (Seikel et al. 2010).

After this process, the eardrum and the three middle ear bones amplify sound waves 26 times before it is sent to the inner ear for further processing (Balkany and Brown 2017).

The Oval and Round Windows

The oval window is a membrane that is located between the cochlea and the inner ear; the sound travels through the three middle ear bones through the oval window. The pressure of the traveling wave on the oval window is amplified 20 times more than on the eardrum due to the difference in the relative surface of the eardrum and the smaller surface of the oval window. The round window vibrates in the opposite direction to the sound vibrations that move in the cochlea through the oval window, therefore, affecting the perilymph of the cochlea (Ruberg 2018). Specifically, the ossicular chain applies sound to the oval window that leads to the cochlea. The round window, located in close proximity to the oval window, moves in reciprocal fashion, expands outwards responding to an inward movement of the stapes footplate, and expands in the opposite direction when the stapes moves away from the oval window (Hawkins 2017).

The Eustachian Tube

An additional part of the middle ear is the Eustachian Tube, which forms the space filled with air between the throat and the nose (Balkany and Brown 2017).

The Eustachian tube is a link between the middle ear and the nasopharynx. The facial nerve (cranial nerve VII) also passes through the middle ear (Munir and Clarke 2013). The function of the Eustachian tube is to allow mucous to flow out of the middle ear and the air (oxygen) to move into and out of it. It is used as an equalizer to balance the pressure levels inside the middle ear – such as in the cases where the atmospheric pressure is altered, i.e., scuba diving and airplane travel (Balkany and Brown 2017).

Evolutionary Status of the Middle Ear

Based on comparative morphology, Reichert's (1837) hypothesis regarding the middle ear in mammals states that two of the mammalian ossicles, the malleus and incus, were derived from cartilages comparable to the lower and upper jaw elements in other amniotes, namely, the articular and quadrate. Additionally, Reichert (1837) suggested that the stapes is comparable to the columella auris in nonmammalians as a component similar to the hyomandibular.

Further evidence from fossil records in South Africa and Russia support the primary jaw joint origin of the mammalian middle ear components. Specifically, these fossils are synsids, a class of animals consisted of the pelycosaurs and therapsids, from which mammals emerged. Also, the mammalian tympanic membrane is assumed to consist of a small dorsal part which is homologous to the reptilian tympanic membrane called parts flaccida, and a large ventral portion homologous to a novel mammalian middle ear feature, the pars tensa (Takechi and Shigeru 2010).

Manley (2010) has reached to a conclusion stating that the tympanic middle ears were developed independently and that the mammalian middle ear is not a better developed single-ossicle

middle ear. Rather, its origin is unique. Manley further elaborated on the fact that evolution in similar groups takes place independently and in parallel most of the time, and the results developed from the same structures could be similar. Also, there is the possibility of a random and opportunistic evolution and that the evolutionary developments of both middle and inner ear were crucial for the development of hearing in very high frequencies. Together with the development of the tympanic middle ear in therian mammals, the brain became larger in size and a secondary palate was developed, having as a result the ancestral pressure-gradient middle ear to be replaced by a pressure system (see Manley 2010, for a review).

Additionally, Maier and Ruf (2016) have explored the question of how the structures of the mammalian middle ear that were developed at the angle of the lower jaw were later relocated to the basicranium (see Maier and Ruf 2016, for a historical review).

Manley (2010) made an interesting comment regarding evolution of the middle ear. He specifically states that

evolution is never goal-oriented. Instead, we must view the evolution of high-frequency hearing in mammals as the fortuitous result of totally unrelated changes in head structures that both led to a new type of middle ear that enabled better transmission of higher frequencies and to pressure-detection middle ears that made the acquisition of high-frequency hearing very advantageous.

Manley (2010) further noted that the process of selection is naturally occurring but the variations are determined genetically between individuals.

Conclusion

The middle ear consists of the three ossicles, namely, the malleus, incus, and the stapes. The tympanic muscles – stapedius and tensor tympani – have as their main function to dampen sound in order to protect the inner structures of the ear. The oval and the round window work to transmit the sound to the cochlea, and the Eustachian tube is to allow mucous to flow out of the middle ear and the air (oxygen) to move into

and out of it. It is used as an equalizer to balance the pressure levels inside the middle ear.

The evolutionary aspects of the middle were also discussed with emphasis to the groundbreaking work done by Reichert (1837). Manley (2010) has provided much insight into the evolution of the middle ear.

Mindblindness

Jeffrey Niehaus

Christopher Newport University, Newport News, VA, USA

Definition

The inability to interpret behavior in terms of goals, beliefs, desires, and other mental states. It is proposed that, to varying degrees, people with autism suffer from mindblindness.

Introduction

“Mindblindness” is both a concept and the short title of Simon Baron-Cohen’s influential 1995 book *Mindblindness: An Essay on Autism and Theory of Mind*. The term “mindblindness” is meant to be an analogy to “colorblindness,” but whereas colorblindness is a deficit in visual processing, mindblindness is proposed to be a deficit in social processing. The concept of mindblindness attempts to take the disabilities central to autism and frame them in terms of a modular, cognitive, and developmental explanation rather than one that is rooted solely in learning or other environmental influences. Mindblindness, therefore, conceptualizes a person with such deficits not as a person who lacks knowledge, experience, or intelligence, but who lacks the necessary equipment to appreciate what it is like to see the world through the explanatory lens of mental states.

Main Text

The term “mindblindness” did not originate with Baron Cohen’s 1995 publication and was in use at least as early as Gopnik’s 1993 unpublished essay “Mindblindness.” While much of the work in understanding mindblindness focuses on people with autism, there is some controversy surrounding the degree to which the cognitive model associated with mindblindness is a sufficient

explanation for autism spectrum disorders. However, instead of being a strictly clinically focused work, the goal of understanding mindblindness is also to achieve greater insight into how a neurotypical person's brain is organized. The utility of the concept is that it allows us to identify and tease out the functional scope of a very important cognitive module, or related set of modules.

Evolutionary Forces and the Adaptive Problem

In his book, Baron-Cohen begins with the insight from Nicholas Humphrey (1983) that humans must have evolved a truly impressive ability to interpret other people's behavior in terms of mental states. The payoff for this ability was not just mere understanding, however. Once the behavior of another organism is fit into the language of beliefs, goals, desires, and personal knowledge, it becomes possible to gain predictive power over what that organism is likely to do next. As this ability began to emerge over evolutionary time, it became ever more important to be good at it in order to compete in the relatively new game of "social chess," an analogy from Humphrey that Baron-Cohen uses extensively. Baron-Cohen quotes from Humphrey (p. 20):

Thus social primates are required by the very nature of the system they create and maintain to be calculating beings; they must be able to calculate the consequences of their own behavior, to calculate the likely behavior of others, to calculate the balance of advantage and loss—and all this in a context where the evidence on which their calculations are based is ephemeral, ambiguous, and likely to change, not least as a consequence of their own actions.

Therefore, the abilities associated with mindreading (which are absent in mindblindness) are conceptualized in explicitly evolutionary terms as an adaptation designed to solve the adaptive problem of predicting the behavior of highly social peers.

The Intentional Stance

Baron-Cohen borrows from the work of Daniel Dennett (1978) who described several "stances"

that one can take in describing an object. There is the "Physical Stance" (in which one describes the parts of an object just how they are and also the cause-and-effect relationships between them), the "Design Stance" (in which one describes an object in terms of a function that it can fulfill), and the "Intentional Stance" (in which an object is described in terms of what it thinks, intends, and wants). While all three stances (or perhaps more, if they were to be discovered and described) *could* be applied to animate objects like people, only the Intentional Stance is efficient and useful enough to help someone navigate an environment filled with people and animals. That is to say, that if one were to try to describe why a person picked up a box of cookies at a supermarket, looked at the side of the box, and then replaced them with a frown, it is theoretically possible to do so by describing the firing of every neuron and the contraction of every muscle involved in the episode. However, even our best neuroscientists cannot provide such detail under the best of circumstances. Similarly, one *could* describe the *functions* of muscles and nerves, and the function of a brain area designed to create behavior that maximizes caloric intake while another brain system represents longer-term health goals and thus may inhibit the appetite system, but such explanations are lengthy and require a good deal of formal education while still being speculative (at least for particular cases). On the other hand, the natural and useful way to explain the behavior would be to say that the person thought the cookies looked tasty and was hungry for them, but then decided to check to see how many calories they had. Since the person wanted to lose weight, they decided to put the cookies back. This quick and efficient interpretation of the behavior puts us in the extraordinary position of identifying the key factors that went into the behavior so that in the future, if those key factors are again present, we can anticipate what the person is likely to do. We can then adjust our behavior accordingly, now that we know how the person is likely to react to the offer of, say, an unhealthy plate of bacon-cheese fries.

The lack of the ability to take the Intentional Stance, then, would rob an individual of an extremely useful tool in social functioning,

including much that makes the pragmatics of language possible. Baron-Cohen proposes in the book that the lack of the ability to “paint” mental states onto observations is central to the diagnosis of autism. He then uses some examples to illustrate what it must be like to be surrounded by behavior that is inexplicable. To quote Allison Gopnik (1993):

This is what it’s like to sit around the dinner table...around me bags of skin are draped over chairs, and stuffed into pieces of cloth, they shift and protrude in unexpected ways. ...Two dark spots near the top of them swivel restlessly back and forth. A hole beneath the spots fills with food and from it comes a stream of noises. Imagine that the noisy skin-bags suddenly moved toward you, and their noises grew loud, and you had no idea why, no way of explaining them or predicting what they would do next.

This vivid example is an extreme version of what it may be like for a person who can only use the physical or functional stances to be surrounded by things that seem to call out for explanation and prediction, and may be something of an approximation of the anxiety which could come with more severe forms of autism.

Conclusion

Mindblindness is a term that describes the lack of ability to interpret and predict behavior in terms of mental states like wanting, knowing, planning, feeling, and thinking. Individuals with mindblindness are forced to try to understand people and animals in purely physical or functional terms, without the ability to reference the inner lives of others. Some proponents of mindblindness make the claim that it is a parsimonious explanation for the range of deficits typically found in autism.

Definition

Mirror neurons are a type of cell in the nervous system that fires during the production of a goal-directed action or expression and during the observation of that same action or expression.

Introduction

Mirror neurons (MN) are a type of neuron, located throughout the nervous system, which discharges both when producing a goal-directed action – such as reaching for an object – and when observing someone else performing that same action. Since the observer's neurons fire as if they are the ones acting, they simulate internally without physically producing the action. Thus, MN provide a link, or a “mirror” between others' actions and our own actions, enabling individuals to experience others'

actions firsthand, as if they were the ones carrying them out. This unique property is how mirror neurons acquired their name.

Main Text

It has been just over 20 years since MN were originally discovered, completely transforming our understanding of the neural underpinnings of social behavior. Indeed, our conceptualization of the motor system has dramatically changed with the realization that the motor system is involved not only in the production of movements but also in the processing of sensory information aimed at supporting the capacity to interpret others' behavior. The team led by Giacomo Rizzolatti discovered MN in the ventral premotor cortex (area F5) in macaque monkeys through extracellular single-cell recordings (di Pellegrino et al. 1992; Gallese et al. 1996), and subsequently these neurons have been recorded in the posterior parietal cortex, an area that is anatomically connected with area F5 (Fogassi et al. 2005).

Since the initial discovery of MN, researchers have made great strides in understanding their properties. Here, some key discoveries are highlighted; however, this is not an exhaustive list. Recent reviews summarize these and other findings in more detail (e.g., a recent edited book on MN: Ferrari and Rizzolatti 2015).

Basic Properties and Related Functions

One of the most intriguing properties of MNs is that their activity appears to be related to the *goal* of the observed or executed actions, rather than simply the body movements. That is, MN are not activated when observing biological movements that mimic a motor act but that are devoid of a goal. MN's activity in monkeys is evident not only for hand actions but also for goal-directed mouth actions (Ferrari et al. 2003). Further, some MNs are sensitive beyond the visual modality, responsive to other modalities, including sound. For example, some MN discharge when hearing actions (audio-visual MNs), such as the sound of

tearing or crumpling a piece of paper (Kohler et al. 2002). Other studies found that these neurons can be activated also when actions are performed with a tool (pliers) that require different movement kinematics and patterns of muscle activity from the natural action performed with the hand (Rochat et al. 2010). The findings clearly support the view that these neurons are capable to code the goal of an action.

MN are hypothesized to have multiple primary functions, including imitation and action understanding (for a review, see Rizzolatti et al. 2014). Imitation refers to the ability to match a modeled action. In order for an individual to match another individual's action, there must be a link between the visual and motor modalities. That is, an individual must be able to see another individual's behavior and match it with motor output. This can be particularly difficult to do if you cannot see yourself perform the action, for instance, if trying to match a facial expression without having a mirror nearby. This is known as the correspondence problem: how does the imitator know what pattern of motor activation matches the model's action? While observing an actor perform an action, the observer's motor representations of that action activates, thereby enabling a first-person experience of the other person's action. Thus, the motor knowledge of the observer is exploited in order to access to the meaning of the observed action. A meta-analysis in humans, involving 11 studies and 361 patients, revealed that lesions within the mirror network are linked to poor action perception and deficits in action understanding (Urgesi et al. 2014). Furthermore, this activated motor representation can be exploited to reproduce the observed action. Brain imaging studies in humans have demonstrated that during the observation and reproduction of simple movements, or also novel patterns of behavior, parietal and premotor cortical regions, corresponding to the human MN system (see below), are recruited.

Existence in Humans

While single-unit recordings have been used to study MN in nonhuman primates, as reviewed

here, this method is not as feasible in humans, unless under specific clinical conditions, given its intrusiveness. One study with electrodes implanted in different brain areas of epileptic patients confirmed the presence of neurons with mirror properties in different brain areas, including the supplementary mesial cortex and the parahippocampal gyrus (e.g., Mukamel et al. 2010). This study, however, did not explore the presence of MN in the homologue monkey areas. The vast majority of MN studies in humans, however, have utilized less-obtrusive neuroimaging techniques – which are indirect measures of MN activity – including functional magnetic resonance imaging (fMRI), positron emission tomography (PET), magnetoencephalography (MEG), as well as neurophysiological approaches, including transcranial magnetic stimulation (TMS) and electroencephalogram (EEG) (for a review, see Oosterhof et al. 2013). These indirect measurement approaches offer convergent evidence of an MN system in humans, namely, the ventral premotor cortex, inferior parietal lobe, and part of the inferior frontal gyrus (e.g., Molenberghs et al. 2012).

Extended Mirror Neuron Network

MN functions are also revealed by the fact that MN exist widely across the monkey brain. In addition to area F5, MN have also been discovered in other cortical areas anatomically connected with F5 and with which they form a functional circuit. These areas include the parietal cortex and the primary motor cortex (M1). Within the parietal cortex, there are MN in both the posterior parietal cortex (area PFG; Gallese et al. 2002) and within the intraparietal sulcus (area AIP; Pani et al. 2014). Other neurons with mirror-like properties have also been described in the monkey supplementary cortex, the dorsal premotor cortex, and in the secondary somatosensory cortex. All these cortical areas have anatomical connections with the parietal and premotor cortices. These new findings support the view of the existence of functional action-observation network with individual nodes decoding different aspects of observed actions, known as the Extended Mirror Neuron Network (Bonini

2016). Studies in humans and in the monkey also suggest that, beyond the decoding of actions, such as grasping and biting, the extended mirror neuron network is involved in the processing of emotional facial expressions. In fact, overlapping brain activity during the observation and execution of emotional facial gestures has been recorded in the anterior insula, a region implicated in integrating autonomic, visceral responses (e.g., Caruana et al. 2011), and also the anterior cingulate cortex.

Development Across the Lifespan

There is also a lively debate surrounding whether MN gain their properties through experience or the extent to which they are genetically hardwired or present already at birth. Like most systems, “nature,” genetics, and “nurture,” everything else besides genetics, including the prenatal and postnatal environments, may contribute to the development of MN and may even work together in interaction through epigenetic processes (Ferrari et al. 2013). Next is a review of evidence that MN are functional from birth and are further tuned through experiences.

There is behavioral evidence that MN are functional from birth, which comes from the discovery of a phenomenon known as neonatal imitation (review Simpson et al. 2014). Neonatal imitation is a precocious capacity to match observed actions, including facial expressions, in the 4 weeks following birth. In other words, if you stick out your tongue at a newborn, the infant is likely to tongue protrude back at you. Neonatal imitation was first reported in humans nearly four decades ago (Meltzoff and Moore 1977) and has since been extensively replicated in humans as well as in chimpanzees and macaque monkeys (for a review, see Simpson et al. 2014). Critically, infants only a few minutes old are able to match facial expressions the first time they see them, suggesting an experience-independent sensorimotor matching ability that is functional from birth. One proposal is that a mirroring system could underlie this early capacity, enabling newborns to solve the correspondence problem (since they cannot see their own faces).

Consistent with this view, neurophysiological evidence also suggests that MN are functional from birth. EEG is a particularly useful noninvasive tool for measuring MN activity for which infants are relatively tolerant and has revealed a functioning MN system is present from birth in monkeys (e.g., Ferrari et al. 2012). Specifically, these studies report that newborn monkeys, while both observing and imitating facial gestures, exhibit similar cortical changes. Termed the “mu rhythm,” cortical activity desynchronizes, or is suppressed, both while observing and producing actions, found in infant and adult human and nonhuman primates.

Role of Experience

Of course, just because MN are present from birth does not imply that they are insensitive to experience. Indeed, EEG studies suggest a functional mirroring system is modulated by infants' early experiences, with macaque infants who have more enriched early social experiences exhibiting stronger MN activation to social gestures, compared to infants with less enriched social experiences (Vanderwert et al. 2015). Further, in the first year of life, infants dramatically improve in their ability to control their own actions and in their ability to understand other goal-directed actions. Developments in infant's action control are intricately linked to developments in their action understanding. MN activation during action observation also depend on whether individuals have a specific action in their motor vocabulary (i.e., whether the observer can produce that specific action). For example, an infant who only knows how to crawl, but not yet walk, will show MN activity while observing a crawling more so than while observing a walking action, whereas an older child, who can walk, will activate MN when observing a walker (van Elk et al. 2008). These results are consistent with findings in adults who vary in their expertise. For example, when dancers observed their own dance style versus another style (in which they were not expert), they exhibited greater brain activity in MN regions, suggesting motor expertise influenced action observation (Calvo-Merino et al. 2005). Similar

findings have been reported for a wide variety of other actions for which you can gain expertise, including musical observation/production (e.g., Vogt et al. 2007).

Evolutionary History

It is relatively uncontroversial that mirror mechanisms are phylogenetically ancient and have a broad evolutionary basis (Bonini and Ferrari 2011). It has been proposed that the different categories of MNs (hand and mouth MNs) might have different evolutionary origins even though, at the cortical level, their functional properties overlap (Casile et al. 2011).

One possibility is that MN began by acting as a monitoring system to track one's own behavior, then evolved as an extended recognition system to enable matching one's behavior with others', and finally evolved to be used in speech perception and production (Bonini and Ferrari 2011). That is, the function of MN may have changed over the course of their evolutionary history, building from more low-level into more complex functions. According to this view, over the course of evolution, the MN system was refined, shaped by each species' unique socio-ecology. MN are found in humans, Old World monkeys (macaque), New World monkeys (marmoset), and songbirds (Prather and Mooney 2015). Both primate and bird MN systems share the fact that they rely on the motor and visceromotor repertoire of the individual (Bonini and Ferrari 2011). Given these similarities, it is suspected that MN are not an evolutionarily recent phenomenon in humans, although MN systems may have been further refined in the human species.

Other Capacities that Involve Mirror Neurons

While the basic roles of MN in imitation and action understanding are relatively uncontroversial, there exist a number of open questions concerning the diverse areas in which MN may

play an important role. Here, a couple of additional areas are reviewed: language and empathy.

While humans communicate mostly by speech, hand gestures are often present as well. In fact, it is widely hypothesized that gestures evolutionarily preceded speech, and the discovery of MN offers support for this view, directly linking two individuals, sending and receiving messages from both hands and mouths (Rizzolatti and Craighero 2007). Imitation is a key factor in learning language; thus in the same way that MN facilitate imitation, they may aid in the acquisition of language. There are several investigations showing that the mirror system is implicated in language processing. For example, Broca's area – a region involved in speech production and considered part of the MN system – is activated by producing or listening to phonemes (i.e., units of sound that distinguish one word from another; e.g., /c/ sound in "cat" vs. /b/ sound in "bat") (Fadiga et al. 2002). Some even speculate that mirror mechanisms are the groundwork from which language evolved, through a first stage in which actions, gestures, and pantomime were involved for social communication (Arbib 2005).

In addition to MN involvement in "cold" action understanding (non-emotional actions, such as grasping an object), MN are also involved in "hot" actions, involving emotions (Rizzolatti and Craighero 2005). The mirror mechanism involved in this case is not confined to parietal and motor regions, but it recruits other brain regions, such as the anterior insula and the anterior cingulate cortex (Wicker et al. 2003). This capacity to share emotions is considered as an important building block for empathy, defined as the ability to share emotions or sensations. While empathy involves a wide array of emotional systems, recent evidence suggests that MN are a critical part of this system. While it is possible to recognize emotions without mirroring or empathy, such as through a more "cold" or cognitive process, more commonly we do so using MN to automatically and effortlessly mirror other people's emotions (Rizzolatti and Craighero 2005). The same principle can be applied to other sensations like pain. Studies have shown that overlapping areas of the brain are activated upon both seeing a loved

one in pain and experiencing pain themselves (Singer 2006). These mirror mechanisms are used to understand how the pain of others feels in order to empathize.

Neurorehabilitation

There are a number of potential clinical applications that may involve MN, particularly those involving motor dysfunction. For example, during a stroke, blood flow to an area of the brain is disrupted and causes damage, often resulting in the loss of voluntary movement. Given that MN are activated both during action production and observation, stroke rehabilitation treatments have focused on action observation, motor imagery, and imitation as part of physical therapy to regain function during stroke recovery (Garrison et al. 2010). MN research has also inspired treatments for autism spectrum disorder (ASD), a neurodevelopmental disorder characterized by motor deficits, language impairment, and social impairment. Although there is much to learn about the role of MN in ASD, there are early promising interventions for children with ASD, which have focused on imitation (for a review, see Iacoboni and Mazziotta 2007).

Conclusion

In summary, it is important to keep in mind that MN systems work in collaboration with other important brain and bodily systems to carry out many of their primary and secondary functions. Neuroscientists recognize that MN are not the *whole story* for explaining the mechanisms that underlie any given behavior or ability. In addition, while there is now a more nuanced and refined understanding of MN since their discovery, just over 20 years ago, there is still much to learn about them. However, despite these limitations, the importance of MN cannot be ignored, as they are widespread throughout the nervous systems of humans, nonhuman primates, and likely many other species, functional early in development, and involved in a variety of foundational capacities.

Mirror Self-Recognition

Brielle T. James and Michael J. Beran
Georgia State University, Atlanta, GA, USA

Synonyms

Self-awareness

Definition

An understanding that one's own reflection in a mirror is an image of oneself, as opposed to

believing that one is looking at another individual. This understanding is evidenced by the use of the mirror to touch and/or investigate normally unseen parts of one's body.

Introduction

Do animals recognize themselves? This question prompted the first studies on mirror self-recognition in nonhuman animals, and subsequent research in this area has generated strong debate about the evolutionary emergence of self-aware aspects of human consciousness. Gallup's (1970) results set the foundation for the comparative study of mirror self-recognition with methods that have since become the standard test of visual self-awareness in animals. Gallup (1970) gave four chimpanzees (*Pan troglodytes*) and six macaque monkeys (four *Macaca arctoides* and two *M. mulatta*) 10 and 14 days, respectively, of exposure to a large mirror placed outside of their cages. All three species initially reacted with social responses (e.g., vocalizations and threat behaviors) directed toward their reflections, as if they were seeing an unfamiliar individual. However, within several days of this mirror exposure, the chimpanzees eventually stopped displaying social behaviors and increasingly used the mirror to inspect normally unseen parts of their body, such as picking food from the inside of their mouth and inspecting their anogenital region (Fig. 1). Macaques, on the other hand, did not show a decrease in social behaviors nor any spontaneous self-directed behaviors. Following this period, the mirror was removed and the animals were anesthetized so a nonirritant, odorless mark could unknowingly be placed on one of their eyebrow ridges and the opposing ear, locations that could only be seen using the mirror. Then, the animals were observed for any mark-directed behaviors – first in the mirror's absence and then its presence. In the absence of the mirror, only one mark-directed touch was observed in total across all of the species. However, with the aid of their mirror image, the chimpanzees frequently directed touches to the marks on their faces, occasionally even inspecting the fingers afterwards that they had used to touch the marks, further

suggesting that they understood the mirror image was an image of themselves. The macaques, however, never made mark-directed responses, suggesting that they may not possess the self-recognition abilities of humans and chimpanzees – a capacity that Gallup (1970) proposed may be limited to humans and the great apes.

Mirror self-recognition thus came to be seen as a behavioral window into self-awareness and the mind. Gallup (1982) defined self-awareness as the ability to become the object of your own attention. Recognizing one's self in a mirror serves as evidence of this "sense of self" (Gallup 1982). Therefore, sessions of mirror image exposure and the mark test provided an objective, nonverbal assessment of mirror self-recognition that could be applied across species, allowing for direct comparisons and study of the ontogeny, phylogenetic organization, and mechanisms of self-awareness. Tests of mirror self-recognition also have been influential for the field of developmental psychology. For example, using similar methods (a mark test and behavioral observations of mirror responses), Amsterdam (1972) documented that mirror self-recognition emerges in human children around two years of age.

Spontaneous mirror-guided self-exploration of body parts that can only be seen with a mirror and the extinction of social responses (as if seeing an unfamiliar conspecific) directed toward the mirror image during mirror exposures, along with mark-directed responses during a subsequent mark test to objectively verify self-recognition, are considered the two criteria necessary to identify an individual's capacity for mirror self-recognition (Anderson 1994; Gallup 1994). Mark tests should be conducted with marks that are unknown and unseen by avoiding any olfactory or tactile cues and by being placed on a part of the body not visible without the use of a mirror (for additional methodological considerations, see Gallup 1994).

Tests of Mirror Self-Recognition with Apes

Given Gallup's (1970) original findings and the strong hypothesis that only humans and great apes have the ability to be self-recognizing, other

Mirror Self-Recognition, Fig. 1 Examples of contingent body (*top*) and facial (*middle*) movements and self-exploratory behavior (*bottom*). From “Self-recognition in chimpanzees (*Pan troglodytes*): Distribution, ontogeny, and patterns of emergence,” by D. J. Povinelli,

A. B. Rulf, K. R. Landau, and D. T. Bierschwale, *Journal of Comparative Psychology*, 107, p. 351. Copyright 1993 by the American Psychological Association (Reprinted with permission)

nonhuman primates soon were tested for mirror self-recognition. Self-recognition in chimpanzees and orangutans (*Pongo pygmaeus*) has been repeatedly demonstrated (e.g., Povinelli et al. 1993; Suarez and Gallup 1981). Spontaneous mirror-guided self-exploration also has been reported in bonobos (*Pan paniscus*; e.g.,

Westergaard and Hyatt 1994), suggesting a capacity for self-recognition in this species as well, although no formal mark tests have been conducted. Research in gorillas (*Gorilla gorilla gorilla*) is less clear regarding their mirror self-recognition ability. Some studies reported no evidence of self-recognition (e.g., Suarez and Gallup

1981) even after close to 400 h of mirror exposure was provided (Ledbetter and Basen 1982). However, instances have been reported of gorillas that passed versions of the mark test, but did not show any mirror-guided self-exploration (e.g., Shumaker and Swartz 2002).

Tests of Mirror Self-Recognition with Other Primates

Prosimians, Old and New World monkeys, and gibbons do not show compelling signs of mirror self-recognition during standard mirror exposure sessions and mark tests (e.g., Inoue-Nakamura 1997; although see Ujhelyi et al. 2000, for an alternative view concerning gibbons). Instead, they seem only able to make social or exploratory responses to their mirror images (see Anderson 1994, for further discussion, and Inoue-Nakamura 1997, for a summary of species tested for mirror self-recognition). This marked difference in responding across primate species supports Gallup's (1970, 1982) assertion that there may be a fundamental qualitative difference in cognition between the self-recognizing primates (humans and the great apes) and all other primates (prosimians, monkeys, and gibbons). However, this hypothesis of an evolutionary gap in primate cognition has been challenged and has inspired numerous efforts to find self-recognition in both primate and non-primate animal species.

Various procedural modifications have emerged in the comparative study of mirror self-recognition to facilitate better evidence of this capacity in species outside of humans and the great apes. One area of focus addresses potential issues of motivation and mark saliency during mark tests. The concern is that mark tests showing a lack of mirror self-recognition in some species may actually be false negatives due to the marks used not being salient (on a perceptual level) and/or motivating enough for the individuals tested. In response to this criticism, Hauser et al. (1995) used a modified mark test with cotton-top tamarins (*Saguinus oedipus*) in which the white tufts of hair on the tamarins' heads were dyed a different color. They reported that while all

of the tamarins that were tested failed a traditional mark test, five of six monkeys touched their dyed hair while looking in the mirror. Hauser et al. (1995) proposed that these self-directed mirror behaviors, while low in frequency compared to humans and the great apes, argue against the hypothesis of phylogenetic discontinuity in self-recognition ability. It should be noted, however, that a replication of this study by Hauser et al. (2001) failed to find the same results, and other studies using food substances as marks in order to increase motivation in several gibbon species (e.g., Suddendorf and Collier-Baker 2009) and marmoset monkeys (*Callithrix jacchus*; Heschl and Burkart 2006) did not find evidence of mirror self-recognition. In addition, Gallup et al. (1980) introduced the use of a directly visible mark (e.g., to the stomach or wrist) during the standard mark test as a control condition to confirm that subjects had at least a general interest in the marks used. This approach rules saliency out as a potential reason for negative results and has been used since by others (e.g., Suarez and Gallup 1981; Suddendorf and Collier-Baker 2009).

Gaze aversion also has been considered a potential reason for the lack of mirror self-recognition in monkeys. Anderson and Roeder (1989) first addressed this concern by presenting capuchin monkeys (*Cebus apella*) with angled mirrors. Similarly, Macellini et al. (2010) presented two pig-tailed macaques (*Macaca nemestrina*) with a modified mark test in which they were prevented from seeing their faces and could only see a mark on their chests using a mirror. However, no self-directed or mark-directed responses were found in either of these monkey species. Attempts to facilitate mirror self-recognition by providing mirror exposure starting early in life and/or for prolonged periods of time (e.g., Anderson 1983; Gallup et al. 1980), physical access to manipulate the mirror (e.g., Anderson and Roeder 1989), and mirror exposure sessions in pairs or groups to utilize monkeys' proficient ability to recognize one another (e.g., Anderson and Roeder 1989; Gallup et al. 1980) all failed to produce evidence of self-recognition in primates outside of humans and the great apes.

Even with explicit training to touch directly visible marks in their environment and on their body (Roma et al. 2007) and to use mirrors to retrieve otherwise unseen food (e.g., Heschl and Burkart 2006; Macellini et al. 2010) in an effort to aid animals' learning of mirror contingency, monkeys still failed a mirror-mark test. Thus, the evidence at this time suggests that prosimians, monkeys, and gibbons typically do not show a capability for mirror self-recognition.

Tests of Mirror Self-Recognition with Non-primate Species

Various non-primate animals also have been studied with self-recognition tests. Two bottlenose dolphins (*Tursiops truncatus*; Reiss and Marino 2001; Fig. 2), one of three Asian elephants (*Elephas maximus*; Plotnik et al. 2006), and two of five European magpies (*Pica pica*; Prior et al. 2008) were reported as recognizing their mirror image as themselves. However, it should be noted that Plotnik et al. (2006) did not require the elephants to be in front of the mirror during mark-directed touches and no mark-directed touches were observed for any of the elephants

in a retest by the researchers two months later. Four killer whales (*Orcinus orca*) also were presented with mirrors and three of the four were given a mark test (Delfour and Marten 2001). The whales demonstrated contingency testing behaviors only in the presence of the mirror (e.g., repetitive head movements and opening of the mouth). In addition, during the only analyzed mark test, a female whale was observed rubbing her mark off against a tank wall away from the mirror and then returning to the mirror afterward. This behavior occurred three times in succession, suggesting possible anticipation by the whale that her mirror image would be different after rubbing the mark off (although no details were given about the whale's behavior during the sham-mark sessions).

In a replication of Prior et al.'s (2008) study with magpies, the same mark test was given to nine jackdaws (*Corvus monedula*; Soler et al. 2014), another corvid species. However, they did not pass the mark test. Two pigeons trained to use a mirror to respond to an illuminated light behind them and to demonstrate self-directed behavior by pecking a directly visible mark on their bodies were then given the mark test and were reported to pass. This suggested "spontaneous integration" of the two behaviors to

Mirror Self-Recognition, Fig. 2 (a) Mark-directed behavior by a dolphin to a real mirror immediately after release from being marked. The faint white line on the wall indicates the location of the mirror. (b) The dolphin at Wall 1, exhibiting late sham-directed behavior: a continuous and repetitive sequence of 12 dorsal-to-lateral-ventral flips exposing the location of the sham-marked area of his body, the underside and tip of the right pectoral fin, to the

reflective surface. This unusual behavioral sequence continued for 32 s (Image is from "Mirror self-recognition in the bottlenose dolphin: A case of cognitive convergence," by D. Reiss and L. Marino, Proceedings of the National Academy of Sciences, 98, p. 5941. Copyright 2001 by the National Academy of Sciences. Reprinted with permission)

demonstrate mirror self-recognition (Uchino and Watanabe 2014). However, self-recognition as a result of explicit training of criterion behavior may be fundamentally different from the spontaneous mirror-guided behaviors seen in great apes (Gallup 1982).

Theoretical Interpretation and Debates About Mirror Self-Recognition

Some theorists do not regard mirror self-recognition as evidence of self-awareness, and a stimulating debate exists around this question. On one side of this debate is the original view of mirror self-recognition as evidence of self-awareness, introspection, and theory of mind (Gallup 1982). However, Heyes (1994) argued that great apes' mirror responses only required the use of visual sensory feedback to guide their behavior and were not different from their ability to successfully navigate their physical environment without running into objects. Similarly, Mitchell (1993) proposed two theories of mirror self-recognition that do not require a self-concept. Instead of recognition of one's own image, Mitchell (1993) suggested that mark-directed responses may only be relying on a combination of kinesthetic-visual matching and an understanding of object and mirror properties. Both Heyes (1994) and Mitchell (1993) also suggested that mark-directed touches may be the result of social responding and imitation.

Conclusion

Despite these differences in opinion about the psychological mechanisms at work, Gallup's (1970) mirror image exposure and mark test procedures have been used for the past 45 years to study mirror self-recognition comparatively. These tests provide a means to better understand the evolution of cognition through testable theories, and mirror self-recognition remains influential to comparative and evolutionary psychology. Although the exact neuropsychological mechanisms of self-recognition have yet to be identified,

there is growing interest in establishing the neural bases for mirror self-recognition (see van Velu and Chance 2014), an approach that likely will add a new chapter to this debate about what it means to recognize oneself in a mirror and how this capacity reflects the nature of nonhuman animal minds.

Definition

The concept that cultural norms and values derive their meaning within a specific social context such that each culture must be analyzed on its own terms.

Introduction

Cultural relativism at its simplest is this: *Judgments are based on experience, and experience is interpreted by each individual in terms of his [or her] own enculturation* (Brown 2008, p. 364). As a simple statement, this seems uncontroversial. However, further examination reveals that it has been misinterpreted in ways that are consequential for anthropological theory and practice as well as for more general philosophical positions.

The term cultural relativism may be parsed with several related but very different meanings.

All of them are rooted in reference to the behavior of people individually or collectively in cultures, subcultures, or even smaller social groups within cultures or subcultures. There are empirical and semantic issues even in this preliminary matter of properly referring to people as part of such entities, but we shall ignore those and take it for granted that one may define “a culture” satisfactorily enough to engage further issues about the relativism of cultures.

Historical Context of Cultural Relativism

The concept of cultural relativism cannot meaningfully be separated from the modern concept of culture, which emerged along with the practice of anthropology in the nineteenth century. Culture came to be understood as everything people know, believe, or habitually do and make as a result of their being part of a group. Proposed as a corrective to theories of geographic determinism and theological explanations for differences among societies, this conception of culture countered Victorian ideas about social evolution, progress, and the nature of non-Western people which were ethnocentric, racist, and supportive of European empirical expansion.

In the early twentieth century, anthropologist Franz Boas proposed the notion of *cultural relativism* in the context of several developments: the anthropological articulation and embrace of the concept of culture, the growing body of work of early ethnographers, reaction against the prevailing theories of cultural evolution, the expansion of Western imperial powers, the growing recognition of the power of enculturation, and the recognition of ethnocentrism as a likely cultural universal. It was articulated more fully by his students, most succinctly by Melville Herskovits. Two kinds of cultural relativism are relevant to evidence gathering about behaviors or interpretation of behaviors within suitably defined cultures. These are *descriptive* or *methodological* cultural relativism (Brown 2008; Womack 1995) and *metaethical* cultural relativism (Gowans 2015).

Descriptive Cultural Relativism

Both ethnographers in the field and anthropology professors in their classrooms typically espouse a

descriptive or methodological cultural relativism that follows directly from Herskovits' original formulation: because people think and act on concepts rooted in their enculturation, if ethnographers want to understand the people, they must at least temporarily suspend judgments based on their own cultures' premises.

Descriptive cultural relativism arises from cross-cultural comparison. The classic philosophical example is Herodotus' descriptions of the Greeks' and the Callatians' mutual horror at how they treated their dead: the Greeks burned corpses and the Callatians ate them (Westacott 2016). The behaviors are distinct descriptively and even logically incompatible given that *if* one of these is *somehow* judged to be wrong, then the other may be a member of a set containing at least one behavior judged right. Of course the Greeks and the Callatians judged their own behaviors to be right, and thus strictly contradictory to the other by their own assessments. However, (classically bivalent) logic recognizes that it is possible that, given some objective criterion of what is *right* in these circumstances, *both* the Greeks and the Callatians may be wrong. This logical observation then gives rise to a view about cultures which can be *described* as divergent with respect to some common human condition (here death) but also *may* be mutually inconsistent with some objective standard of being morally correct.

Metaethical Cultural Relativism

If one assumes that either the Greeks or Callatians are right, the other is wrong. That would produce the claim that there is moral contradiction. As allowed above, even if there is some intercultural objective standard of right *that is in fact lacking in all* observed cultural behaviors and beliefs with respect to some common phenomenon, then *all* those behaviors could thus be properly judged wrong. Some investigators, probably motivated by the logical possibility that since many such descriptively divergent behaviors (observed to be different with regard to the traits, behaviors, or beliefs under consideration) may all be wrong with respect to some supposed objective moral standard, made the further argumentative move to conclude that *no such intercultural objective*

standard exists. This is *metaethical cultural relativism*. By this view, no culture may be judged as right or wrong with respect to any behavior as compared with other cultures, even though each culture judges itself in these ways. This eliminates the very possibility of the *moral* contradiction of descriptively divergent behaviors among cultures.

However, no set of such descriptively distinct and culturally relative behaviors – even an open-ended set – can *itself* entail that there is no such objective standard. *There is no valid reasoning – even an inductive basis – to infer from iterated citations of a lack of agreement of descriptive behaviors cross-culturally that there is no objective intercultural standard for all such behaviors* (Gowans 2015; Rachels 1999). The usual way to express this criticism is that one may not infer values from facts (or vice versa) or even, as here, conclusions *about* values from facts (Hume 1983).

No avenue of human reasoning based on descriptive cultural relativism leads inevitably to metaethical cultural relativism. Metaethical cultural relativism may be true, but *no amount of ethnographic data itself demands that it be true*. Any supposition of metaethical cultural relativism, then, creates difficulties for social scientists and for policy makers.

Misinterpretations

Let us look at a number of ways in which a simple idea (one's judgments are based on one's enculturation) has been misinterpreted as or conflated with other ideas which obscure the primary value of cultural relativism to social scientists. First, while culture is a dominant concept in anthropology, cultural *relativism* is not cultural *determinism* and does not rule out other influences on human society and psychology (Spiro 1986). Cultural relativism does not logically entail normative relativism, which claims that there are no universally or absolutely binding moral principles, nor epistemological relativism, which claims that all ways of knowing are equally true. Herskovits, for example, was emphatic that anthropology can be scientific as well as hermeneutic and urged anthropologists to seek universals through empirical research (Spiro 1986, p. 264). Anthropological definitions of culture invariably include some

notion of culture as shared by a group (however large or small). *Cultural* relativism, therefore, does not entail or require *individual* moral relativism, and indeed every group recognizes and negatively sanctions deviant behavior by its members.

Particularly important in the context of a globalized political economy is that cultural relativism does not entail tolerance. The commonly accepted idea that it does was prompted by the debate surrounding the Universal Declaration of Human Rights in the 1940s. The conflation of relativism and tolerance was readily accepted and persists today, especially among anthropologists in the United States. The central insight of cultural relativism is enculturation, not tolerance. Although anthropologists and sociologists practice a suspension of judgment while conducting fieldwork, the attempt at objectivity is a requirement of the scientific method, not of relativism. Nor does cultural relativism require a kind of cultural romanticism, “a naïve glorification of all that is non-western” (Womack 1995, p. 51). There is no necessary connection between cultural relativism and a conclusion that all cultures are equally “good” or that no criticism of varying cultural practices is ever warranted (Edgerton 1992).

Because cultural relativism does not rule out the possibility of absolute moral standards (which could exist in the universe independent of any culture) or of universal moral standards (shared by virtually all human cultures and which could change over time), it does not rule out the possibility that a set of universally accepted human rights can be discovered. The misconception that relativism is opposed to universalism has sometimes made anthropologists ambivalent participants in the support of universal human rights agendas, not least because individual rights, individual autonomy, and democratic practices are so highly valued in Western society. These values could be discovered to have a universal basis, but so far, this has not been demonstrated. Further, cultural relativism does not require that ethnocentric demands, made by one society or group upon another, always be disallowed (Renteln 1988, p. 64). This point becomes more relevant as globalization of the political economy proceeds apace.

Current Social Science Research Strategies

Let us now consider briefly a number of “hot” research topics that engage social scientists, political activists, and philosophers: clitoral excision, honor killing, veiling and seclusion of women, circumcision of infant boys in Western medical practice and in traditional Jewish practice, arranged marriages, rape as a weapon of war, enlisting child soldiers, exploitation of sex workers, gun control, abortion rights, etc. These pose serious challenges to cultural relativism which, although logically flawed and empirically unsupported in its common, metaethical form, continues to be a position held by many and vilified by many more. Understanding such cultural practices is the goal of anthropological research.

For anthropologists, the basic assumption of cultural relativity continues to hold: ethnographers strive to suspend judgment until a belief or practice can be understood within its total context because they generally accept that enculturation powerfully influences ideas and behavior (the ethnographer’s own and those of the observed people). Ethnographers also strive toward objectivity in data collection and analysis to the extent that they wish their work to be considered scientific. Anthropologists in the field today recognize explicitly the collaborative nature of ethnographic research, i.e., the ethnographer doesn’t directly “collect data” but works with informants who share their knowledge. They acknowledge the power differential that may exist between ethnographer and the observed groups, including efforts to minimize the difference by consulting the group about publishing sensitive material, avoiding politicized use of cultural knowledge by states and other outside groups, and enlisting group members in development projects and movements for social change. Although anthropologists originally studied people in non-Western, often colonized, societies, contemporary anthropologists also study up the power gradient, including literate groups who speak the native language of the ethnographer and powerful groups in the anthropologists’ own culture (e.g., organ transplant surgeons, corporate leaders, nuclear scientists).

Conclusion

Although misinterpreted and misused in various ways for nearly as long as the concept has existed, cultural relativism remains an important corrective to imperialistic and chauvinistic ideologies and a necessary insight for conducting ethnographic research. The unencumbered proposition that judgments are based on experience and experience is interpreted by each individual in terms of his own enculturation directs us toward important areas of basic research. We need to better understand, among other things, the power of enculturation, how people acquire the values of their group(s), the nature of interaction, the ubiquity of ethnocentrism, the porous boundaries of social groups, and the effect of power differentials among groups within societies. The empirical search for universal human values, if discovered, would provide a basis for global assertion of a non-Western ethnocentric set of human rights.

Definition

The result of the rate of the development of technology and civilization occurring faster than natural selection and evolution can occur.

Introduction

Evolutionary mismatch is a phenomenon by which the rate at which our technology has advanced, especially postindustrial revolution, has effects on our bodies and psychology that were not anticipated and cannot be adapted due to the slow rate at which evolution occurs. Ancestrally, our minds and bodies are still designed to

essentially be hunter-gatherers, with the evolution of bipedal locomotion, our diets, and our intelligence that allow us the use of tools to hunt and use in order to increase the chances of survival. Thus, although it has been a considerable amount of time since our ancestors were forging the African savannah, enough time has not yet passed for our bodies to fully change and adapt in response to the recent advances in technology. Due to the industrial revolution in the late eighteenth and early nineteenth centuries, we have had an exponential rate of growth with our development in technology (Ashton 1997). While the industrial revolution spawned things such as factories and machine usage, it also drastically changed everyone's daily life, generally promoting a cleaner, higher quality living due to the commodities available, plus the surplus of new jobs that came as a result. Since then, we've seen development of technologies that were only figments of people's imaginations – things such as having the Internet, smartphones, self-driving cars, airplanes, and so forth. Mismatch represents the idea that our bodies were simply not created for this kind of lifestyle that happened fairly recently, and therefore we are “mismatched” with our physiological, ancestral minds and our modern, technologically advanced environment (Raichlen and Alexander 2014).

Evolutionary Mismatch: Diet

Evolutionary mismatch occurs in a variety of ways and can yield both positive and negative results, although the lion share of consequences tends to be negative. One of the biggest ways that we see mismatch today is in our diets. Our bodies were designed for high levels of physical activity, being able to run long distances and endure heavy cardioactivity. We also developed the tendency to lean toward sugars, salts, and fats because of their evolutionary advantage. When vegetation and livestock was short in periods such as winters or heavy climate fluctuations, sugars, salts, and fats were essential to survival given their ability to be stored in the body. When long periods of famine would occur, those who had indulged in sugars, salts, and fats when these were available had a

higher likelihood of surviving because of their fat storage and were able to live off of that rather than searching for more food. As a result, these foods were also a rarity and, when found, were extremely valuable. Individuals who had a preference to consume higher amounts of sugars, salts, and fats outlived those who did not stock on such foods.

Nowadays, we live in a civilization where everything can be purchased through an exchange of currency. Our bodies evolutionarily did not anticipate the ability to have a currency within a civilization and therefore be able to pay for anything that we may need. Thus, eating is no longer an arduous task of having to go out, hunt prey, skin and cook it oneself, and consume it – rather, we simply go to the local grocery store, buy some meat, and cook it. This completely eliminates the element of the massive amount of physical energy that was expended to simply get a meal. As a result, we see things such as obesity and heart disease as a result of lack of physical activity. Our ancestors were never required to set aside time to exercise given that physical activity was necessary and automatically came included in the hunter-gatherer lifestyle if one was to survive. Given that now we have commodities such as online retailers that can even deliver things to our doorsteps, the amount of physical activity we do in a day is incomparable to what an early hominid would have had to endure. We generally set aside time to engage in exercise, and when we do, we experience benefits such as drastically lowered risk of cancers, heart disease, obesity, and even psychological benefits such as elevated mood and lowered risk for depression. When this need is not met, we fall victim to many diseases and psychological detriments, which is a classic example of mismatch given that our bodies were meant to endure heavy physical activity every day – something that is simply not necessary with the resources we have available to us today (Frassetto et al. 2001).

With regard to sugar, salt, and fat, we now have the ability to simply pick up any foods we wish at the supermarket. Many of these foods are taken advantage of by their respective companies by using *supernormal stimuli* to appeal to

consumers. Thus, high levels of salt, sugar, and fats are often added to products to appear tastier and therefore keep the consumer coming back for more. This is another example of evolutionary mismatch – given that those foods were extremely rare in ancestral times, we developed an affinity for those tastes because, evolutionarily, our bodies were steering us in the direction of getting tastes and foods suitable for survival. Now that these foods are so often readily and easily available, it is extremely easy to overindulge in them, resulting in many of the health problems that we face today. Our ancestors never had to worry about things like diabetes and heart failure because it was simply impossible for them to encounter such a surplus of sugars, salts, and fats such that it would ever be a concern (Gluckman and Hanson 2004). In addition, by simply trying to get a meal, they engaged in rigorous physical activity on a daily basis which also eliminated much of the risk of health- and diet-related diseases. Given the society we live in, we must be attentive to what we eat, such as our sodium levels, cholesterol, intake of vitamins and minerals, and calorie count to avoid facing these detriments. Having to do so is an example of evolutionary mismatch given that our physiological bodies are still adapted to a lifestyle meant for survival on the African savannah, rather than living in major cities with supermarkets, delivery systems, and transportation.

Evolutionary Mismatch: Social Groups

Another common example of mismatch in humans has to do with the social circles we have today versus the one's in which our ancestors evolved. Prior to the advent of agriculture, our ancestors never stayed put for long. Instead, they lived in small nomadic groups, and because groups of thousands would be impossible to manage and coordinate, early hominin societies consisted of approximately 150 individuals (known as *Dunbar's number*). Additionally, a lot of these clans included many families, to the point that a single individual was probably related to a good portion of the group and the whole group

helped in rearing the children (a term known as *alloparenting* described in another section). After agriculture, however, our clans rapidly evolved into more complex societies, eventually leading to the cities we have today. Within a day alone, we may encounter hundreds, if not thousands, of individuals, and the vast majority of them are bound to be strangers. This may lead to higher levels of stress and feelings of loneliness because we are not meant to be so far away from kin.

If our minds evolved around small groups, then what can we possibly do to solve the mismatch between our EEA and our current metropolises? Wilson's (2011) *Neighborhood Project* seeks to answer part of this question by applying an evolutionary perspective on urban planning. Wilson gathered data on students in Binghamton, NY, and examined the nature of neighborhoods that corresponded to students who were doing well academically and socially and how these differed from the neighborhoods of students who were having problems academically and socially.

Beyond the effects of socioeconomic status, evidence suggested that students who lived in neighborhoods with higher levels of social connectedness and social capital performed better in school and scored higher on indices of natural altruistic tendencies. This was true even for children who came from poor areas of the city. Having signs of social connectedness such as decorations during holidays (Christmas lights in December or Easter eggs for April) or interactions among neighbors seemed to make quite the difference in children's development, both academically and socially.

Evolutionary Mismatch: Education

Gray (2011) applied the idea of mismatch to child development across the school-aged years to assess how modern educational systems compare to systems used in prewesternized societies. In current hunter-gatherer societies, education takes a drastically different form because there are not any lines drawn between work, play, and education. The way through which children learn about

the world and how the group works is by merely being part of the group and playing with all the other children. Furthermore, most of the education that children receive does not come from an adult, but from other children, often those who are slightly older. That most seminomadic societies studied had mixed-age environments suggests our ancestors evolved in similar ways and that our minds are not designed to sit in classrooms of same-age children for long periods of time. Gray's findings also suggest that play is essential for child development and learning.

It is not hard to see the disparity between education in ancestral environments and education in much of the westernized world. Children are asked to remain seated and quietly pay attention to an older, adult figure for hours at a time, with very short breaks between classes that are not enough play for their young ancestral minds. Children who cannot follow these rules or who are jittery in class are typically seen as either problematic or perhaps diagnosed with disorders such as attention deficit disorder (ADD) or attention deficit hyperactivity disorder (ADHD). While there certainly is more to these disorders than just mismatch, it is worth considering that a great part of hyperactivity in children is due to the way we evolved to simultaneously play, work, and learn.

Conclusion

For most of our evolutionary history, we lived in small groups composed greatly of blood relatives. It is under this environment of evolutionary adaptedness that our minds acquired the psychological mechanisms we have today. We are the product of thousands of generations of natural selection, yet because evolution is a slow process, the best these selection processes can do is equip us with the same mechanisms our ancestors had in the probabilistic-based "guess" that the environment will remain more or less the same (Geher 2013). Although this usually works out fine, sometimes contexts change over a short period of time, and that has certainly been the case with our environment.

This mismatch between our EEA and modern life can help explain several of today's problems, such as increased obesity and type II diabetes, particularly among developed countries that can more easily and cheaply produce processed foods and exploit our preferences for sugars and fats. It can also shed light on how current systems of education and urban planning are failing by constantly moving further away from models found in seminomadic societies. Although going back to our hunter-gatherer ways is probably not the solution (especially with today's massive population), we can certainly apply evolutionary theory into trying to overcome any mismatch. By knowing how our minds evolved, we can better understand where mismatches lie, and we can even design methods to overcome it by building our communities to resemble those we had during our EEA.

Definition

Evolutionary mismatch occurs when a trait that evolved in one environment decreases fitness or well-being in a later and different environment.

Introduction

This entry describes evolutionary mismatch hypotheses in general form, provides illustration by way of a pair of nonmoral examples, then formulates the *moral mismatch* hypothesis. It then provides an example of a specific moral mismatch hypothesis focused on the tendency to objectify morality, describing the past benefits of this tendency as well as its current costs and suggesting those costs are due to significant differences between modern and ancestral social environments. The overall aim is only secondarily to defend this particular moral mismatch hypothesis; primarily, it is to identify the conceptual, methodological, and evidential issues that arise when formulating and supporting moral mismatch hypotheses.

Evolutionary Mismatch

An evolutionary mismatch is “a situation whereby an organism that evolved in one environment develops a phenotype that is harmful to its fitness or wellbeing in another environment” (Lloyd et al. 2011). Schematically and more generally, evolutionary mismatch involves the following four

elements: a trait (call this T), at least two environments – the past (E1) and the current (E2) one – and some form of cost (C) of T in E2.

A classic case of evolutionary mismatch is the peppered moth (*Biston betularia*). In preindustrial England, a light-colored morph of this moth predominated. As the industrial revolution proceeded, and as pollution darkened the formerly pale bark of the common trees, a dark-colored morph came to predominate.

To put this case into the framework laid out above, T was color, specifically the light coloration, E1 was the preindustrialization forests while E2 was pollution-darkened forests, and C was a fitness cost: T was selectively disadvantageous in E2, as light-colored moths were conspicuous against dark backgrounds and so faced increased predation risk. (For more detail on this case, see Cook 2003; Grant 1999; Kettlewell 1973.)

A case of mismatch involving humans is, plausibly, our “sweet tooth” (Symons 1992). Humans typically prefer sweet foods to bitter ones; this is T. In ancestral environments (E1) where meeting nutritional needs was challenging and efficient energy capture was crucial, the adaptive benefit of T is clear, since sweeter foods are typically more energy dense (e.g., ripe versus unripe fruit). In many contemporary human nutritional environments (E2), however, energy sources are overabundant and T can prompt overconsumption, leading to health costs.

This second example shows that C can be stated not in terms of fitness (although there may well be fitness costs to T in E2) but rather in terms of welfare or well-being. Obesity and health problems can run counter to the interests of the individual, but not *necessarily* reduce fitness. This example also shows why mismatch hypotheses can matter: understanding the causes of a problem is an important step toward developing a solution, and insofar as a mismatch hypothesis contributes to that understanding, it is significant.

With the framework and examples in place, it should be clear that there is no one thing – the mismatch hypothesis – but rather more and less demanding versions of a mismatch claim, depending on how the placeholders in the hypothesis are filled in. A more demanding version

would be that an adaptation that was adaptive in some past environment is now maladaptive. This version restricts the trait to adaptations and the costs to fitness costs. A less demanding version may be that a previously adaptive trait (whether or not it was an adaptation) is now maladaptive. A less demanding version still would be that some previously beneficial trait (whether the benefits were to fitness or not) is now costly (whether the costs are to fitness or not). Clearly, different evidential standards must be met to satisfy differently posed – more or less demanding – versions of the mismatch hypothesis, and clarifying this at the outset of a discussion is useful in avoiding later confusion.

It is now clear how to develop a moral mismatch hypothesis. Doing so requires specifying a trait *T*, describing relevantly different environments *E*₁ and *E*₂, and identifying the costs *C* of *T* in *E*₂. While this is simple enough as a schema, filling in details swiftly becomes complex.

Specifying *T*

Take the trait first. What is *T* in a *moral* mismatch hypothesis? Defining “morality” is far from straightforward (Gert 2012). Evolutionary explanations of morality target phenomena as diverse as systems of norms (Boyd and Richerson 2005; Richerson and Henrich 2012), moral emotions (Prinz 2007; Frank 1988) and the faculty of moral judgment itself (Joyce 2006; Hauser 2006). There are hard conceptual and empirical questions here, about the nature of morality and about which human features are the proper targets for evolutionary explanations of morality. For current purposes, it is possible to remain neutral on what is necessary and sufficient for something – a belief, judgment, utterance, system of rules, etc. – to count as moral, and on what evolutionary explanations of morality should aim to explain. Focus can be placed instead on features of actual moral thought and talk, and consider their evolutionary explanation and current effects.

An important distinction to make at the outset is between the *content* and the *form* of our moral judgments. Selective forces may well have influenced *what* we think is morally right and wrong, good and bad, favoring judgments that

promote survival and reproduction and shaping the content of human morality to the point that “our moral judgments are thoroughly saturated with evolutionary influence” (Street 2006, 114). A distinct claim is that evolution has affected *how* we think about moral matters, in particular, whether we see morality as objective. Perhaps we have been selected to see morality as objective because “human beings function better if they are deceived by their genes into thinking there is a disinterested objective morality binding upon them” (Ruse and Wilson 1986, 179).

There may well be scope to develop a moral mismatch hypothesis with reference to the content of our moral beliefs. Here, a moral mismatch hypothesis focused on the form of moral judgments will be outlined. In particular, this section will develop the idea that our commitment to moral objectivity is a case of moral mismatch. As befits the aim of this section, the primary concern is to highlight the conceptual, methodological, and evidential issues that arise in presenting moral mismatch hypotheses.

In the moral mismatch hypothesis considered here, *T* is the tendency to objectify morality. A natural question to ask immediately is: do we really have that tendency? There is a growing body of work investigating the metaethical views of ordinary folk and the ways in which those views manifest in behavior: the so-called psychology of metaethics (Goodwin and Darley 2008, 2010, 2012). This literature has been especially concerned with whether the folk are objectivists about morality, and if so how that particular metaethical stance matters. Landmark studies in this field were conducted by psychologists Goodwin and Darley.

Goodwin and Darley start with a definition of “moral objectivism” (following Sayre-McCord 1986): objectivism about morality is the view that “moral claim[s] can be true without reference to the subjective states of the individual making the judgement[s], and without reference to the conventions of any group of people who are making the moral judgement[s]” (2010, 163). The test for objectivism – about moral or any other sorts of claims – worked like this: subjects were given various statements and asked (i) to rate their

level of *agreement*, then (ii) if they thought there was a *correct* answer about whether that statement was true or false, and (iii) whether, if someone *disagreed* about the truth of that statement, then either that person or the subject *must* be wrong. Answering “yes” to (ii) but “no” to (iii) makes sense only if one supposes that the truth of the relevant statement is *not* objective in the above-defined sense. If one thinks that the truth of the relevant statement *is* objective, then one should answer “yes” to both questions. Saying “yes” to (i) and (ii) for any particular statement was therefore taken to mean one was an objectivist about that statement.

Goodwin and Darley found that, for the moral claims, the majority of subjects were objectivists (see their 2008 for details), but that there was variation both across individuals in whether they considered moral statements to be objective, and across moral statements in how likely they were to be considered objective. That is, some *subjects* more so than others treated moral statements as objective, and some moral *statements* more so than others were taken to be objective. Congruent findings about moral objectivity have been reported by other researchers (Wright et al. 2013, 2014; Sarkissian et al. 2011). In sum, empirical investigations paint a complex picture, on which ordinary moral agents are significantly but not universally or uniformly objectivist about morality.

The nuance here helps illustrate how filling in the specifics of a moral mismatch hypothesis swiftly becomes complex. Even defining the trait is far from straightforward. Mismatch hypotheses should be open and sensitive to messy empirical detail. In the case of objectivism about morality, it would be too strong to say the trait is universal and perhaps still too strong to say it is even species-typical. More cautiously, the claim could be that a tendency to objectify morality is a feature of some moral agents’ cognitive profile. What proportion of agents is a further question, but not one it is necessary to settle here. This highlights another important lesson from this case. Consider again the “sweet tooth” example: not everyone *has* a sweet tooth, but formulating a mismatch hypothesis about that trait is not for that reason

impossible. So, insisting that the supposedly mismatched trait be universal is too strong a requirement to impose on a mismatch hypothesis.

Another important lesson from this example is that projecting current traits backward in time is not always straightforward. In the peppered moth example, establishing the presence of the mismatched trait in the ancestral population was simple, since it was a case of observable microevolution over short timescales. When the ancestral population in question is further removed in time, though, establishing the presence of the supposedly mismatched trait is harder. It is far from impossible, of course. Consider again the “sweet tooth” example. Part of the case that this is an adaptation come from comparative evidence: other primates too prefer ripe (i.e., sweeter) to unripe fruit. That the trait is shared across nearby branches of our evolutionary tree helps support (though of course does not establish) the claim that the trait was present in the ancestral populations of interest.

Turning to the moral mismatch hypothesis, the question would be: why think the moral trait under consideration was possessed by our ancestors in the past environments of interest? This question is particularly challenging because the kinds of evidence described above are not available. The timescale obviously means simple observation cannot reveal our distant ancestors’ moral behaviors, beliefs, emotions, or systems of rules. Nor is comparative evidence available. (However permissive one might wish to be in deeming other, nonhuman animals moral, it is implausible in the extreme to think *either* that chimpanzees, for instance, are not only moral beings but also have views about metaethics, specifically objectivist ones, *or*, that even if they did, we could ever be in a position to know.) Establishing the presence of the mismatched trait in ancestral populations is a problem that may not have an easy solution. Here, the goal is simply to highlight the challenge. Any fully developed moral mismatch hypothesis – whatever the particular T is supposed to be – would need to properly address it, which may represent a significant evidential burden.

Specifying C

For a given T, a moral mismatch hypothesis needs detail regarding C, the costs of T in E2. Continuing with the case of moral objectivism, the question would be: what costs does objectivist moralizing impose? Here, as elsewhere, the specific example is intended to illustrate general issues for moral mismatch hypotheses.

Goodwin and Darley's findings suggest that ordinary people's metaethical views, in particular moral objectivism, influence attitudes and behavior, and do so in a way that bears on the case for moral mismatch. Objectivism influences how "open" or "closed" subjects are when confronted with moral disagreement. "Openness" and "closedness" are measured by how comfortable a person is being near others with different moral views, what kind of personality judgments a person makes about others who hold different moral views, and by how strongly a person resists changing their moral views in the face of disagreeing others. Goodwin and Darley found that those who treated a moral issue as objective gave more "closed" responses to disagreement on that issue: they showed more discomfort with proximity to disagreeing others, were more likely to say that a disagreeing other was "not a moral person," and were less likely to admit the possibility of giving up their own belief.

Similar results have been reported by other researchers (Wright et al. 2014) who found that being a moral objectivist predicted greater intolerance across a range of measures, including not only comfort with proximity but also willingness to help and cooperate with people who held conflicting moral views.

So, C in the moral mismatch hypothesis considered here can be stated in terms of the problems moral objectivists face when confronted with moral diversity. In such situations, possessing T seemingly makes one more prone to conflict and less able to negotiate resolutions to conflict when it does occur. Notice this is a quite loose statement of C. The currency is not specified. It is certainly not biological fitness, but rather, something more like a prudential cost, to be understood in terms of agents' prudential interests. And, little

has been said about the mechanisms by which the costs of T are imposed. Is it via brute physical fighting, or social strife, or both, or something else entirely?

Here the concern is not primarily to elaborate on the specific example of a moral mismatch hypothesis, but rather to highlight general issues for any hypothesis of this sort, and here is a significant one: stating C clearly, with reference to both the currency and the mechanisms of the cost.

Still with regards to costs, it is worth considering which individuals are the bearers of a mismatched trait's costs. A natural idea here is that the individual who bears the mismatched trait bears the costs, and in many cases, such as the peppered moth and sweet tooth examples used earlier, this is so. But, for a start, the bearers of mismatched traits need not be the only individuals negatively impacted by those traits. For moral mismatch hypotheses that focus on the content of moral beliefs, the costs of mismatch plausibly also fall on individuals other than the trait-bearers. When racism motivates violence, or limited altruism fails to motivate charity, those affected by discrimination and altruism failure suffer. Indeed, it may be that bearers of the supposedly mismatched traits themselves do not suffer at all; for them, there is no cost to T. While this is all quite speculative, a real lesson remains: mismatch hypotheses must be careful in accounting for costs, not only in terms of the currency paid, but also of who pays.

Returning to the specific example, one might wonder whether the costs of objectifying morality are balanced by any benefits of doing so. This usefully raises several questions for mismatch hypotheses of any sort. One is simply whether T in E2 imposes a cost. Another is whether T in E2 confers any benefits. Yet another is whether T is costly on balance, that is, whether it generates a net cost even when any counterbalancing benefits are considered. As emphasized throughout this section, there is no single way to run a mismatch hypothesis. A mismatch hypothesis could claim only that T in E2 imposes a new cost that it did not impose in E1 (remaining silent on whether

the trait in E2 in on-balance costly), or, it could make the stronger claim that T in E2 is on-balance costly. The important thing is to be clear about which claim is being made.

Specifying E1 and E2

It is not enough for a mismatch hypothesis to show that some trait is costly. That is consistent with the trait always having been costly. If that were so, the notion of *mismatch* would be doing no work. A mismatch hypothesis must show that T is costly *because* of some environmental shift. That is, mismatch hypotheses must specify E1 and E2, and, crucially, identify a difference between E1 and E2 that explains why T in E2 is costly. That last point is important, since it highlights the fact that mismatch hypotheses need not give exhaustive specifications of the two environments, but rather enough relevant detail to draw the significant contrast between them.

For the moral mismatch hypothesis being developed here, the C of T in E2 is being prone to conflict when confronted by moral diversity. In arguing that this is a case of evolutionary mismatch, the key idea is that human social life has undergone a radical and evolutionarily fairly recent shift.

From approximately 75,000 years ago until approximately 10,000 years ago, our Pleistocene ancestors were cooperative hunter-foragers living in small, mobile, multifamily groups of 20 to 30 individuals. Call this our ancestral environment, E1. It was characterized by relatively small-scale, homogenous, and independent social worlds.

In the social circumstances that prevailed in E1, a tendency to objectify moral demands may well have been beneficial. Experimental work in moral psychology (Young and Durwin 2013) suggests that being an objectivist about morality boosts motivation to behave as one believes morality demands. In small-scale ancestral social worlds, this extra motivation could plausibly have provided fitness benefit by encouraging intragroup cooperation. Such benefits may have accrued to individual group members – via increased generation of cooperative benefits and decreased risk of harms associated with selfishness and defection – as well as to the group itself, insofar as intragroup cooperativeness is an

important determinant of success in episodes of intergroup cultural selection (see Boyd and Richerson 2005).

Approximately 10,000 years ago, during the Holocene revolution, human social life underwent a dramatic change. The advent of agriculture saw a great increase in group size as well as social complexity. (Groups also became more sedentary, though that is less relevant here. For more on the Holocene transition, see Sterelny 2014a, b.) Contemporary human social worlds are very large, complex, and interconnected. So, the key change when it comes to filling in the moral mismatch hypothesis being developed here is this: whereas ancestral social worlds were relatively small-scale, homogenous, and independent, modern social worlds – E2 – are relatively much larger, more heterogeneous, and interdependent.

While a tendency to objectify morality may well have been adaptive in small-scale, relatively homogeneous and independent ancestral social worlds, it now operates in a much different social context. As a consequence of the change from E1 to E2, modern humans are currently confronted far more often with diversity along many dimensions, importantly including moral diversity, due to both within-group heterogeneity and intergroup interaction.

Recall the findings of Goodwin and Darley and Cole-Wright et al. concerning the influence of objectivism on attitudes toward moral disagreement. Objectivist moralizing may well be harmful under current social circumstances, insofar as it makes agents faced with moral diversity more prone to conflict while simultaneously less able to negotiate and resolve it. If something along these lines is true, the specific moral mismatch hypothesis outlined here would gain some support.

Of course, a great deal more would need to be done to establish that particular version of the moral mismatch hypothesis, but the point of the exercise here is to identify general issues. One such concerns the kinds of environmental change that can generate mismatch. One possibility is that conditions that once obtained no longer obtain, resulting in T in E2 being costly. That was what happened in the peppered moth case: the trees' bark was no longer predominantly white, so, white coloration was no longer adaptive but

instead became maladaptive. Another possibility is that the past conditions persist but new conditions arise that render a previously (and still partially) beneficial trait on-balance costly. This may well be what is going on in the “sweet tooth” case. A taste for sweetness is not entirely unreliable as a guide to getting sufficient energy and nutrition, even though it is now confounded by the ready availability of modern foods. In the case of moral mismatch sketched here, the environmental change is probably more of the former sort than the latter, but the same need not be true of all moral mismatch hypotheses. The important thing is to recognize scope for variation in how mismatch hypotheses are constructed.

Conclusion

Evolutionary mismatch hypotheses can be stated schematically in terms of a trait T, an earlier (E1) and a later (E2) environment, and some cost C of T in E2. A moral mismatch hypothesis can be stated by appropriately filling in these placeholders. There is no single moral mismatch hypothesis, though, since there are multiple ways of filling in T, C, E1, and E2. Depending on how a specific moral mismatch hypothesis is formulated, different conceptual, methodological, and evidential challenges will arise, some of which this entry has identified.

Definition

Mitochondrial DNA is a small circular double-stranded DNA molecule found within mitochondria. Unlike the nuclear genome, it is only inherited from an organism's mother.

Introduction

Mitochondria, covert rulers of the world, are the tiny energy factories of the cell. These membrane bound organelles create energy by using oxygen to burn the food we eat in a process known as

cellular respiration. Floating freely, they exist in hundreds to thousands in the cytoplasm of cells and look much like other rod-shaped bacteria. In fact, over a billion years ago, their prokaryotic ancestors slipped inside other cells and developed a beneficial relationship with their hosts that ultimately facilitated the rise of all eukaryotes, which include protists, fungi, plants, and animals. Only their small circular DNA hints at mitochondria's former independence as free-living bacteria.

Function and Inheritance

Single-celled organisms ruled the Earth for billions of years. Then, around 2 billion years after the first microbe, life got more complicated when cells started dividing up their labor. Some tissues became in charge of digestion while others for motility, storage, and degradation. Cells organized themselves into structures able to communicate and share resources. However, this new complexity demanded a much higher energetic cost. Scientists believe that a large cell swallowed the bacterium ancestor of modern mitochondria, who was then spared from degradation (John and Whately 1975). In exchange for a home, mitochondria produce energy through a chain of chemical reactions that pass an electron down a membrane – giving it the nickname “powerhouse of the cell” (Philip Siekevitz coined this term in his 1957 article “Powerhouse of the Cell.” In recent years, the phrase is usually mocked as an example of useless information taught in schools. In April 2013, a Tumblr user posted several impractical things learned in school, including “mitochondria is the powerhouse of the cell.” In the following 2 years, the post was reblogged and commented on over a million times.) The number of mitochondria in a cell is dependent on what task it needs to accomplish (Robin and Wong 1988). For example, heart cells are powered by thousands of mitochondria while skin cells have almost none. On average, each cell contains around 400, totaling 10 million billion in the human body.

Over millions of years, mitochondrial DNA (mtDNA) has shrunk. Since being engulfed by

our common single-celled ancestor, mtDNA has lost most of its genetic material to the nucleus. In humans mtDNA contains only 37 genes in comparison to the nucleus's 20,000 (Andrews et al. 1999). Most cellular functions are carried out by the host cell, so there is no need for mitochondria to keep redundant DNA. Like bacteria, mitochondria reproduce by exactly replicating their double-stranded DNA and dividing into two. This happens independent of whether their host cells divide because the organelles have their own propagation mechanism, a kind of confined priesthood (Clayton 1982). As each cell contains at least hundreds of mitochondria and each individual mitochondrion has five to ten copies of its DNA, cell division is immensely energy-intensive. MtDNA lost all of its non-vital genes in order to be efficiently replicated and only spans around 17,000 base pairs in vertebrates (Martin and Herrmann 1998). That makes up only .0005% of our entire genome. Unlike our superfluous genome full of transposable elements and repetitive elements, mtDNA genes are compact. (Only 2% of the genome codes for proteins. The rest of it is considered "junk DNA," a term coined by Susumu Ohno in 1972. Whether or not it serves a real purpose is debated among geneticists but may provide new signals for regulation or novel gene functions.) There are no introns, noncoding DNA within a gene, and little noncoding material between genes – a gene immediately starts where another one ends.

Of the genes that remain in human mtDNA, 13 code for proteins involved in cellular respiration and the rest for molecules that transport and assemble amino acids into proteins. All of their functions are closely tied to the control over cellular respiration (Chomyn et al. 1985). The speed of these metabolic reactions is sensitive to the changing energy needs of the cell it resides in, and this can shift rapidly depending on the situation. Mitochondria need to work much faster when we are running a marathon than when we are sitting on the couch watching a movie. (A jog around the neighborhood requires aerobic respiration – oxygen is used by mitochondria to break down glucose to generate ATP or cellular energy. Your breathing rate increases during exercise in

order to adjust for the higher oxygen demands needed by your muscles. Experiments by Gary Dudley in 1982 showed that high-intensity running boosts mitochondrial production.) These changing demands require mitochondria to respond individually to the cell's needs. The mtDNA retains its few genes because they are vital in maintaining a level of on-site control: the chemical reactions needed for energy production are tightly controlled at the level of each mitochondrion. The cell would not be able to respond rapidly or efficiently if mitochondria were controlled by genes nestled far away in the nucleus.

Vertebrates inherit their mitochondria only from their mothers, because the few mitochondria attached to sperm are actively destroyed at fertilization (Sutovsky et al. 1999). The egg contains around 100,000 mitochondria in stark contrast with the wiggling sperm who only has a few arranged around the head to fuel its journey to the uterus. When sperm penetrate the egg, any mitochondria that slip inside are rapidly cut apart by the CPS-6 protein, which first digests the organelle's internal membrane and then the mtDNA (Zhou et al. 2006). This means that the origin of all mtDNA in every cell in your body comes from the few in your mother's egg at fertilization.

Like the Y chromosome, mtDNA has no opportunity for recombination as it is passed down almost unchanged from mothers to their children, both females and males (Giles et al. 1980). Autosomal chromosomes, which contain the majority of your genetic information, go through a complex shuffle every generation, but mtDNA has a straightforward pedigree. Over time, mutations arise in mtDNA which allows it to act as a record of human descent. If a woman acquires a random mutation in her mtDNA, she will pass it to all her children, and her daughters will also pass it onto their children. Therefore, when we find evidence of identical mutations in mtDNA, it indicates that the families who contain them share a common lineage.

MtDNA mutation rates seem to be relatively constant, so scientists can assume that the more mutations there are between two individuals, the longer they have been separated. Specific areas of

the mtDNA evolve at a rate of up to ten times than nuclear genes (Brown et al. 1979), which can be used to study differences at the population level. In 1987, geneticists examined the mtDNA of modern humans living around the world and concluded that they had a common descent in Africa around 200,000 years ago (Cann et al. 1987). But that was not even the most spectacular discovery; their analysis indicates that all people living today can trace their mtDNA back to a single woman – dubbed Mitochondrial Eve. This was not the first human woman but instead the most recent common mitochondrial ancestor; all of the other women roaming the Earth at the same time as her left no heirs living today.

A long time ago in a galaxy far, far away, director George Lucas told us the story of Jedi Knights filled with intelligent microscopic life forms called midichlorians that resided symbiotically in all living cells (In the *Phantom Menace*, Qui-Gon discovers that Jedi Anakin Skywalker has the highest known count of midichlorians. This incredibly high count, and therefore connection with the Force, is the reason why he was the only human who could pod race despite more there being more experienced pilots). In large amounts, they allow for a connection with the omnipresent energy field called the Force. Their similarities to mitochondria in both name and function are indisputable. Like midichlorians, mitochondria are intracellular symbionts related to ancient bacteria with their own separate DNA. This genetic material is also why Princess Leia's son is a Jedi: mitochondria is inherited from your mom.

Conclusion

The mitochondria found in every eukaryotic cell was once an independent bacteria. Over a billion years ago, they crawled inside other cells to form the symbiotic relationship that is found in almost every plant and animal cell. They are membrane-bound organelles that create most of our cells's store of energy and still retain their own genetic information. In comparison to the nucleus's 20,000 genes, mitochondrial DNA contains just 37 genes—the majority of which are involved in

oxidative phosphorylation. Mitochondria, and all of its genetic material, is maternally inherited and passed on to offspring in the cytoplasm of an egg cell.

Mobility: Crawling and Walking

Lana B. Karasik
College of Staten Island and Graduate Center,
City University of New York,
New York, NY, USA

Synonyms

[Locomotion](#); [Motor development](#)

Definition

Posture – prone or upright – is the position of the torso required to keep balance while stationary (e.g., sitting) and while moving (e.g., crawling and walking). Crawling is locomoting in a prone posture by moving all four limbs, sometimes with belly on the floor for added support. Walking is locomoting forward bipedally without external supports.

Supported by NSF Grant DLS-1349044 and DLS-1528831 to Lana Karasik, Catherine Tamis-LeMonda, and Karen Adolph.

Introduction

One of the crowning achievements in infancy is acquiring the ability to locomote. The study of crawling and walking has a long history (Preyer 1905; Trettien 1900). In more than a century of work, researchers have focused on defining crawling and walking age norms and painstakingly described developmental changes in coordination, movement patterns, and muscle activations (Adolph and Robinson 2013). Much of this work has been conducted in Western populations, overlooking culture and context and assuming universals. Cultural beliefs, practices, and expectations manifest in childrearing practices – how to hold, dress, sleep, toilet, etc. The variability in childrearing – or differences in infants’ experiences – offers different opportunities for posture, balance, and locomotion, which in turn explain variation in motor skills. Moreover, variability in motor skills extends beyond infancy. Examples of this variability and effects of everyday experiences are evidenced in cross-cultural comparisons. The aim of this entry is to show how cultural research illustrates the formative role of experience in motor development and challenges our assumptions that differences in childrearing have no effects on crawling and walking (Adolph et al. 2010; Karasik et al. 2010).

Historical Considerations

In the early 1900s, development was seen as a function of neurological maturation and physical growth. Arnold Gesell (1928) and the early pioneers of motor development led the charge in documenting the developmental progression of postural and locomotor skills based on behavior of infants from a homogeneous sample (infants from middle-class families of Northern European descent living in New Haven, CT), presumably to reduce much of the already existing variability in motor skills. Gesell was first to recognize the enormous variability: In hundreds of pages, miles of film, and dozens of photographs, he meticulously described stages of prone progression and upright locomotion for each month of life

of these children (Gesell and Ames 1940). In this enormous endeavor, Gesell acknowledged the historical and cultural shifts that could underlie variability in motor skills (Gesell and Ilg 1943) but focused on establishing commonalities in infants' skills, assigning ages at onset, and revealing skill order. Gesell's detailed records were condensed to "milestone" charts – a limited list of skills that Gesell considered essential (e.g., hand and knee crawling over other forms of prone progression), ordered by age. Variations of motor milestone charts are still prominently displayed in pediatric offices, featured in developmental textbooks, and are foundational to widely used scales of infant and child development – e.g., Brazelton, Bayley, Peabody – all normed against Western European standards. The World Health Organization took it a step further by publishing standards – requirements for the sequence and timing of infant postural and locomotor milestones – that all infants should meet (Martorell et al. 2006).

Despite their use in clinical diagnostics, norms and standards oversimplify the development of skills like crawling and walking by placing the emphasis on *when* skills should emerge rather than *how*. Ultimately, age is only mildly related to crawling and walking, and importantly it does not determine onset. Instead, infants' experiences created by childrearing practices are a better indicator of what skills develop and how.

Shared Childrearing, Different Practices, and Constraints on Motor Skills

How are babies put to sleep? Where are infants situated when awake? What are parents' choices for diapering and toileting? Universally, caregivers deal with these matters, but how they do so can vary widely by culture and context. Western parents have nearly infinite options on how to manage daily childcare routines, with abundant, commercially available baby gear offering potential solutions. Spacious cribs, thin disposable diapers, baby walkers, and playpens are only a few frequently used childrearing tools readily available to Western parents— and all inadvertently

place a premium on self-generated movement. It is surprising that there are little empirical data describing the frequency and the extent of use of these practices within Western cultures and around the world. Possibly, the paucity of data is because researchers have taken childrearing practices for granted, presuming that variability in these practices present more of a nuisance rather than signifying important differences in infants' experiences.

Handling and Containing Infants

Ask any American parent how to hold a newborn, and they will answer – you must support the baby's head. Western parents deeply believe that babies are to be handled with extreme care, gently cradled in arms with the head always supported against gravity. Specific recommendations published by experts across Europe emphasize safest positions for infants, when to use water for grooming, and whether to rub the skin during bath (Blume-Peytavi et al. 2009). In other parts of the world, caregivers use more vigorous approaches to handling. Intense massage, daily exercise, and close body contact are common childrearing practices documented across Africa in communities such as Kipsigis and !Kung San (Konner 1976), the Gusii (LeVine and LeVine 1966), the Bambara (Bril and Sabatier 1986; Rabain-Jamin and Wornham 1993), Cameroonian Nso (Carra et al. 2014; Keller et al. 2002), and in the West Indies (Hopkins and Westra 1988). Especially during bathing routines, caregivers thoroughly and intensely give infants a rubdown, kneading the head and body, rotating the joints, and pumping the legs and arms. They toss infants into the air, suspend them by the neck or from the ankles, and grasp them by each limb, (Fig. 1a) thus allowing infants to practice supporting their heads against gravity (Hopkins and Westra 1988; Rabain-Jamin and Wornham 1993; Super 1976). Caregivers in these cultural communities believe that the physiological flexion – the tight muscles and joints – infants are born with will not dissipate unless babies are stretched and massaged (Rabain-Jamin and Wornham 1993). The release of

M

Mobility: Crawling and Walking, Fig. 1 Culturally specific practices in infancy and adulthood. (a) Suspension by neck, ankles, or limb. (b) Moving the arms and legs to train crawling and walking. (c) Restriction in slings,

“gahvora” cradles, or baby walkers. (d) Locomotion in “lotus” shoes for bound feet, high heels, or “huarache” sandals

physiological flexion may increase the range of motion, thereby providing more opportunities for spontaneous movement.

The vigorous handling may look intense, but only to the Western eye. Caregivers who engage

in these handling routines do so because it is integral to childrearing; it is what caregivers think they should be doing as part of normal everyday interactions to ensure healthy development (Carra et al. 2013; Heidi Keller 2003). In

addition, mothers from West Africa noted that the handling and body stimulation allows for positive social interactions. While infants jump in mothers' laps, babies see mothers smiling and laughing in response (Carra et al. 2014; Super 1976). The reciprocal exchange sets a foundation for turn-taking during these "protoconversations."

Ideas about the importance of childrearing practices are so fervent that even if caregivers emigrate, they often continue their traditional practices rather than relinquish them to adopt those of the host culture. For instance, West African immigrant mothers living in Italy and France and Jamaican immigrant mothers living in Britain maintained frequent body stimulation and exercise routines (Carra et al. 2013; Hopkins and Westra 1990; Rabain-Jamin and Wornham 1993).

Childrearing practices are not without consequence. Infants who were regularly massaged and exercised (Fig. 1b) shortly after birth began walking at earlier ages than infants who did not experience daily massage and exercise (Hopkins and Westra 1990; Rabain-Jamin and Wornham 1993). Experimental data confirm the effects of childrearing. How parents hold their young infants was found to be related to infants' level of postural control in sitting and standing (Duncan et al. 2018). A few minutes of postural training at 2 months of age accelerated postural, manual, and locomotor skills at 12 months (Lobo and Galloway 2012). A few minutes of daily crawling exercises accelerated the development of crawling in 7-month-olds (Lagerspetz et al. 1971). A few minutes of daily stepping exercises in 2-month-olds increased stepping movements 2 months later (Zelazo et al. 1993) and accelerated walk onset age by the end of the first year (Zelazo et al. 1972).

When not tossed, suspended, or exercised, caregivers situate infants in places that keep them safe and occupied or tote them along as they do their own work (Fig. 1c, left and middle panels). African infants in Mali, Kenya, and the Ivory Coast, Papua New Guinea, the Ache infants of Eastern Paraguay, the Zinacanteco of Maya, and Tajik infants in Central Asia spend time confined to slings and sacks tied to caregivers' bodies or gahvora cradles (Bril and Sabatier 1986;

Karasik, Ossmy, Tamis-LeMonda, & Adolph 2018; Kaplan and Dove 1987; LeVine and LeVine 1966; Solomons and Solomons 1975; Tracer 2009). Zinacanteco infants of a Mayan community in Mexico are carried on their mother's back in a "rebozo" shawl that is wrapped around the infant and knotted over the mothers' chest. When mothers are unavailable, older siblings take over carrying but rarely playing with infants. During the first year, infants are not held upright to look around; their face in the rebozo is often covered. Family members avoid talking with or engaging infants in face-to-face interaction and rarely put them on the floor to explore or move on their own (Brazelton et al. 1969). Tajik infants in gahvora cradles are also covered, but caregivers respond contingently to babies' whimpers and cries. During their first year of life, Ache infants spend the majority of their day carried by caregivers and rarely set down on the ground or left alone (Hill and Hurtado 1996).

Caregivers actively discourage exploration to guard children against environmental hazards. To restrict exploration away from caregivers, mothers tie children with a vine around the ankle so that they don't wander into the fire. When camp is moved, infants are carried in a sling with their heads resting on mothers' chest. At 18 months, infants are taught to ride on top of their mother's carrying basket, holding on to her, and ducking branches and vines in the path. As a result, the Ache lag months behind American children; walk onset age is around 2 years of age in Ache infants as compared to 12 months in American infants (Kaplan and Dove 1987). But later in childhood, the Ache children are encouraged to move and explore. At about 5 years of age, children are required to walk 3–5 km over difficult Paraguayan forest terrain when camp is moved; boys are taught to build and use bow and arrow; and girls weave and carry "burden baskets" of personal belongings and food when camps move (Hill and Hurtado 1996).

Caregivers in the USA also reduce opportunities for locomotor exploration by putting infants in playpens and highchairs and installing safety gates that restrict access to stairs. Infants with limited access to stairs learned to go up and

down stairs at older ages as compared to infants with stairs in their home (Berger et al. 2007). Caregivers use mechanical baby walkers in which infants are propped up sitting with their feet dangling (Fig. 1c, right panel). The walkers typically have trays with attached toys for manipulation and play, but these fixtures limit infants' view of the ground and feet, preventing them from visually guiding their movements. Although their feet may reach the floor, infants do not maintain posture and balance on their own as they passively glide across the surface. Infants who used baby walkers crawled and walked later than those who never did or who used baby walkers that did not obstruct infants' view (Siegel and Burton 1999).

Sleeping and Swaddling

Placement and positioning during sleep impose different constraints on movement, and both practices have undergone historical and cultural shifts. Until the early 1990s, caregivers placed infants to sleep in a prone position to prevent aspiration of regurgitated milk. In 1992, the American Academy of Pediatrics instituted the "Back to Sleep" movement, which urged caregivers to put infants to sleep on their backs because researchers found a positive association between the prone sleep position and Sudden Infant Death Syndrome (SIDS). This shift to back-sleeping resulted in a decrease in SIDS ("Changing Concepts of Sudden," 2000). However, the change in infants' sleep position came at a cost: back-sleeping is related to an increase in brachycephaly (flattened back of skull), plagiocephaly (flattened side of head) (Argenta et al. 1996; Chizawsky and Scott-Findley 2005; Holt 1960; Turk et al. 1996), and torticollis (weakened neck muscles on one side of the head) (Boere-Boonekamp and van der Linden-Kuiper 2001). Exclusive back-sleeping position was related to delays in prone skills. Infants who are put to sleep on their backs displayed delays in rolling, tripod sitting, creeping, crawling, pulling to stand, and playing with hands at midline relative to prone sleepers (Davis et al. 1998; Jantz et al. 1997; Vaivre-Douret et al. 2005). It is possible that receiving fewer opportunities to practice

pushing themselves up and developing strength needed to move on all fours delayed infants' prone skills.

Swaddling – which often accompanies back-sleeping – is a well-known form of restriction, characterized by cloth used to wrap infants' body and limbs. Ancient Greeks swaddled infants because they believed it facilitated proper postural development (Lipton et al. 1965). In the traditional Navajo and Mohave cultures, swaddling involves using a cradleboard. Infants are swaddled and bound against the solid surface of the board with their limbs straightened and held in place with straps made of cloth, willow bark, or twine (Chisholm 1978). The cradleboard can be hung by hooks or carried in caregivers' arms or on their backs to keep infants close as caregivers work (Chisholm 1978; Dennis 1941). Recently, swaddling became popular in the USA and Europe likely because research suggested that swaddling reduces excessive crying (Giacoman 1971; Lipton et al. 1965) and improves quality of sleep (van Sleuwen et al. 2007). Although swaddling involves the deliberate restriction of limb and body movement, researchers have found no consistent evidence that swaddling delays motor development (Chisholm 1978; Manaseki-Holland et al. 2010). It is possible that caregivers may reduce how much they swaddle at various points in development or modify the practice, thereby reducing the potential effects of movement restriction (Manaseki-Holland et al. 2010).

Toileting and Dress

Methods of toileting and dress affect infants' spontaneous movements. Caregivers begin to toilet train at widely disparate ages across the world – as early as 4 months among the Digo of East Africa (deVries and deVries 1977) to as late as 2.5 years of age among modern middle-class families in the USA (Brazelton 1962). Before children can fend for themselves, caregivers invent toileting solutions that align with the geographic, economic, and cultural context in which they raise their children. In Tajikistan and other

parts of Central Asia, caregivers toilet using an external catheter that drains waste from infants bound in a gahvora cradle (Karasik et al. 2018). In rural China, caregivers placed infants on their backs for most of the day, buried up to their armpits in a bag of fine sand (Xie and Young 1999). The gahvora cradle and sandbagging are effective methods for keeping infants clean and dry in areas where water and other resources are limited. But, the restrictive bindings and heavy sand prevented infants from moving; infants showed delays in gross motor skills relative to WHO standards (Martorell et al. 2006; Mei 1994). In other parts of China, caregivers dress newborns in split crotch pants and learn to “read” infants’ signals (Dombroski 2018). Similarly, Vietnamese parents potty-train their babies using a whistle. When the baby fusses or gives a sign that they need to go, parents hold them over the toilet and whistle. Caregivers are able to toilet train their babies by 9 months of age, more than a year before Western parents initiate training (Horn 2006). By 12 months, infants could communicate their need to go and by 18 months could go independently without needing to ask (Duong 2013).

Western diapering methods seem less extreme. Until the 1960s, cloth diapers were almost universal in use; by 1971, thin disposable diapers had become the primary means of toileting (Krafchik 2016). However, both types of diapers affect infant movement. While wearing old-fashioned cloth diapers or modern disposable diapers, infants showed less mature walking patterns and displayed more missteps and falls compared to when they walked naked (Cole et al. 2012). Possibly, the diaper pushes infants’ legs apart, making movements more awkward and balance more precarious. Going naked, infants’ gait was advanced by months as compared to when they walked in diapers. Like diapers, layers of clothing can impede infants’ crawling and walking. Infants in Japan, the USA, and Israel show delays in crawling if they are dressed in restrictive heavy clothing (Atun-Einy et al. 2013; Benson 1993; Hayashi 1992). At the turn of the twentieth century, 40% of infants skipped crawling altogether, possibly because the long gowns that were

popular at the time prevented locomotion on hands and knees (Trettien 1900).

Expectations and Activities Shape Ways of Moving

Similar to assumptions made about triviality of childrearing in infancy and extent of variability in infants’ experiences, researchers have assumed the narrow range of motor outcomes beyond infancy. We assume that the epitome of mature locomotion is walking, as exemplified by college-aged participants. But undergraduates that often contribute to psychological research are not representative of the proficiency of adult locomotion. Expectations and culture-specific activities affect typical locomotion for adults and define what is socially accepted and functional in their community.

Expectations

Crawling, a transient behavior displayed in infancy prior to walking, has been documented as a primary mode of locomotion in a few exceptional adults (Humphrey et al. 2008; Tan 2006; Turkmen et al. 2006). Researchers discovered a family living in remote villages of Turkey where the adults crawled on hands and feet instead of walking bipedally. One of the reasons for their stunted development is that children’s parents did not encourage them to walk. Other siblings crawled, thus providing the expected social model of typical locomotion (Adolph et al. 2010).

Expectations about body dimensions, posture, and quality of movement in adults are important factors for social desirability and status in the community. The practice of foot-binding for women prevailed in China for hundreds of years (Ebrey 1999; Kenny and Nichols 2017; Ko 2005). Chinese women bound their daughter’s feet when girls were between the ages of 4 and 6, while bones in the foot are fairly supple, but beyond the developmental time frame when children acquire mature walking gait (Adolph and

Robinson 2013). The ideal female foot (Fig. 1d, left panel) was only 3–4 inches in length (Fang and Yu 1960; Reznikov et al. 2017). The size of the feet created a wavering posture resembling a “lotus flower in a breeze,” which signified women’s tenderness and submissiveness. And the tight binding forced women to take small steps, which was thought to strengthen their vaginal muscles, enhancing their value in marriage (Ping 2000). Moreover, foot-binding limited women’s mobility and productivity and was therefore reserved for wealthy families who did not rely on the labor of their wives and daughters. Women in poor families were still required to do work such as spinning, weaving, tending crops, and food preparation that required skill and strength of hands, not feet. To achieve the ideal foot took years: Mothers submerged daughters’ feet in hot water, scrubbed off dead skin, and wrapped cotton bandages soaked in hot water around the foot folding the four toes under the ball of the foot, leaving the big toe out. Girls were then forced to walk on their folded feet, weakening and breaking the bones, allowing their feet to be tied more tightly (Ko 2005). The practice in China was outlawed in 1912 but continued until 1949 in rural areas (Kenny and Nichols 2017).

High heels (Fig. 1d, middle panel), designed to lengthen and enhance the shape of the legs, also have effects on movement by transferring the center of gravity upward, thereby transforming posture and balance and reducing stability. Wearing high heels also is a century-old tradition associated with upper-class women and men (Vartanian 2011; Wiedemeijer and Otten 2018). High heel use begins in young adulthood and requires extensive practice. Wearers must learn to adjust their posture and modify walking gait to avoid appearing hunched over and stomping ape-like. When walking in high heels, walkers changed the placement of the foot, adjusting their posture at the shoulders and neck, slowed down their speed, and took shorter steps than when walking barefoot (Chien et al. 2013). With experience, high heel wearers learn to adopt a walking strategy to maintain efficient control and minimize trips and falls (Chien et al. 2014).

Daily Activities

People’s daily tasks shape locomotor skills. In Nepal and Africa where transportation is lacking, children and adults routinely carry extraordinary loads up to 70% of their body weight for great distances (Heglund et al. 1995). They carry loads supported on their heads rather than in arms over rough terrain and without compromising efficiency or mechanical energy (Bastien et al. 2016). Walking with head-supported loads begin in childhood to accomplish daily activities and to train for work as porters. Over years of practice, walkers with head-supported loads learn to change the biomechanics of their normal gait patterns to conserve energy, making their walking gait more efficient than adult walkers without such experience (Heglund et al. 1995).

The Tarahumara of the Copper Canyons in Northern Mexico are another prime example of how culturally specific tasks push locomotor abilities beyond what we typically think is the limit. The Tarahumara are known for their extraordinary ability to run long distances, up to 250 miles, without running shoes, either barefoot or in thin, rubber, makeshift sandals called huarache (Fig. 1d, right panel) held on with leather laces (McDougall 2009). Their extraordinary running abilities are not limited to only a select few elites; the entire tribe runs: men, women, and children of different ages, sizes, and body types. And the Tarahumara can run for days. Why do they do it? They run to complete daily tasks, such as delivering mail or persistence hunting for food. They run for comradeship, to maintain interpersonal connections among the tribe. And they run for amusement, competing in races of up to 300 miles. How do they do it? The Tarahumara have inhabited the secluded mountainous region of the Copper Canyons for nearly 500 years (McDougall 2009). Over years of running starting in early childhood, the Tarahumara have adapted their bodies and running ability to the physical constraints of their rugged environment. The trick to their long distance running ability without incurring injury turns out to be barefoot running. When researchers tested participants in the lab running in sneakers and while barefoot, they found that

impact during heel strike was minimized when running barefoot rather than when running in sneakers (Thompson et al. 2015). McDougall's bestselling 2009 book revolutionized the running shoe industry. The minimalist, "barefoot" running movement inspired the creation of new, funny-looking five-finger shoes to mimic the effects of barefoot running (Davis 2014). It is still unclear whether running barefoot or in the minimalist running shoes really does reduce injury (Perkins et al. 2014). But the message seems to be for adults and for walking infants alike: it's best to go naked or barefoot.

Conclusions

What we know about motor development depends on whom we study, what we ask, and where we collect the data. Current cross-cultural work on motor development is narrow in scope. Much of the world is unrepresented. The World Health Organization (2006) that published standards of gross motor skills all infants should meet only included infants from six countries, ignoring many regions of the world (e.g., Central America, Australia, Central Asia). Thus, with respect to daily childrearing tasks, we know little about what caregivers do, when they do it, and how much.

Experience affects every aspect of motor development, and childrearing practices – the most mundane everyday routines – shape infants' experiences. Cross-cultural research helps us realize the extent of the variability in everyday experiences. However, the literature is limited because everyday experience is typically overlooked or poorly documented, studies are concentrated within infancy, and the focus is predominantly on age comparisons. Particularly, the field of cross-cultural motor development is dominated by comparisons with Western practices and age norms established on Western populations, as if Western childrearing practices and developmental outcomes are the barometer for what is universal or at least what is optimal.

Typically, the extent of the variability of experiences or its effects on motor development are not well understood. If experience is considered, it's

treated as a dichotomy – infants are exercised or not, carried or not, diapered or not – because comparisons are made with Western practices where the practice exists or is absent. At best, mothers are asked to self-report whether they engage in an activity: never, sometimes, or often (e.g., Hopkins and Westra 1990). This type of quantification of childrearing assumes that practices either promote or inhibit particular behaviors. But childrearing practices are on a continuum. Take the case of sling carrying, for instance. On the one hand, the practice is restrictive because infants' opportunity to roam and explore their environment is removed. But, to some extent some aspects of posture and balance are actually facilitated: to hang on, infants must be able to adjust their balance and posture to keep upright with mothers' adjustment in posture as she bends and moves (reviewed in Bril 2018). Some researchers have emphasized the effects of carrying in a sling (Goldberg 1972), finding a positive correlation between sling carrying and advanced motor behavior at 6 months but not at 12 months. This finding suggests that there is not a direct relation between postural stimulation during carrying and motor performance; the same experience has a positive effect at 6 months but a negative at 12 months, possibly for different reasons. It is important to examine cultural practices thoroughly, across cultures and age, before concluding that a childrearing practice affects motor outcomes.

The limited work on effects of experience that has been done is concentrated in infancy. But changes in motor skills occur throughout the life span and are specific to a culture. Crawling or walking, teetering on bound feet or in high heels, and running barefoot or in toe pocket shoes are only a few examples of culturally specific expectations and activities that shape movement in adults, well beyond the anticipated endpoint of motor development.

The prevailing focus on age comparisons ignores other outcome measures that can expand our knowledge about motor development (Adolph et al. 2010). In addition to onset ages, experience can alter the rate of developmental change, so we can know how quickly skills

change over time and when asymptote is reached. The very form of movements and which skills are acquired in the first place can also be shaped by experience.

Cross-cultural comparisons serve as a natural experiment about experiences that fit within specific cultural contexts and can lead to the same or different motor outcomes (e.g., Adolph 2018; Bornstein 1995). Thus, cross-cultural research provides an incredible opportunity to understand plasticity, resilience, and effects of experience.

Modeling Language Transmission

Jon W. Carr and Kenny Smith
School of Philosophy, Psychology and Language
Sciences, University of Edinburgh, Edinburgh,
UK

Definition

Languages adapt as they are transmitted from one generation to the next. Modeling language

transmission in computer simulations and laboratory experiments shows how this process gives rise to the structure found in language.

Introduction

Language is a defining characteristic of our species, so understanding its evolutionary origins is central to understanding human evolution. In their seminal paper, Pinker and Bloom (1990) argued that the evolution of language is best understood as the result of conventional Darwinian processes, just like other complex biological traits. However, languages themselves also adapt and evolve over repeated episodes of learning and use, providing two evolutionary mechanisms that shape language: the biological evolution of the human capacity for language *and* the cultural evolution of language itself. This entry outlines the consequences of cultural evolution for language and gives examples of how modeling language transmission can shed light on how language evolved.

Cultural Evolution and Language

Like many other human behaviors, language is socially learned and culturally transmitted: Humans learn the language of their speech community by observing the linguistic behaviors of other members of that community. More specifically, languages are transmitted via *iterated learning*: A language is learned by observing the linguistic behavior of another individual who learned their language in the same way. That humans are able to learn language presumably reflects some cognitive capacity or combination of capacities that is unique to humans (Hauser et al. 2002). However, repeated episodes of learning and use also allow for the cultural evolution of languages: Linguistic variants that are difficult to learn, impose substantial processing burdens, or do not meet the communicative needs of language users will tend to be replaced by those that are more learnable, easier to process, or more

functional (Christiansen and Chater 2008). This is because the mistakes that language users make during learning, and the modifications they make while communicating, tend to be in favor of more learnable, more functional forms; poorly adapted variants will be replaced by superior ones. Cultural evolution thus gives rise to languages that are well adapted to being transmitted from one generation to the next.

Mathematical, computational, and experimental techniques developed over the past two decades have made it possible to systematically investigate how cultural processes shape language (see Kirby et al. 2014 for a review). This line of research has demonstrated that some of the fundamental properties of language can be explained as products of cultural evolution, thus highlighting the importance of understanding the role of culture in explaining language design and reframing the debate on the biological evolution of the language faculty (Thompson et al. 2016). This entry reviews some of this work here, focusing on experimental models of the emergence of compositional and categorical structure in language.

Cultural Transmission Gives Rise to Compositionality

Language is compositional: The meaning of a complex utterance is a function of the meaning of its parts and the order in which those parts are combined. By combining a set of linguistic units in a particular order (e.g., *the dog bit the man*), a language user is able to form a complex meaning that is systematically related to an utterance that uses a different set of words (e.g., *the cat bit the man*) or that places the words in a different order (e.g., *the man bit the dog*). This compositional structure is central to the expressive power of language; with knowledge of the linguistic units and rules of combination, language users are able to produce and understand any complex utterance—even those that have never been encountered before.

In the first work of its kind, Kirby et al. (2008) ran an experiment showing that the property of

compositionality can emerge as a result of language transmission, replicating the results of earlier computer models (e.g., Kirby 2002). Participants had to learn an “alien” language which consisted of words for colored moving shapes. After a training phase in which participants observed the objects together with their labels, participants were prompted to recall the labels for those objects. The responses of a given participant were then taught to a new participant, whose responses were in turn taught to another new participant, thus modeling what happens when languages are transmitted between individuals (Fig. 1a). Each transmission chain was initialized with an unstructured, non-compositional language in which every object was associated with a randomly generated label. After around ten generations of the iterated learning process, linguistic systems emerged that exhibited compositional structure. An example of this result is shown in Fig. 2a. The initial input language taught to the first participant in a chain contains no system-wide structure, but by the ninth generation, the language had evolved a compositional system in which the first syllable encodes color, the second syllable encodes shape, and the final syllable encodes movement.

Compositionality Depends on Transmission and Communication

Languages are not merely transmitted from person to person via learning and recall; they are used for communication, and the communicative use of language provides the input to language learning. This means that language is shaped by two pressures. On the one hand, a language needs to be expressive—it should allow its users to convey important distinctions when communicating. On the other hand, it also needs to be learnable. These pressures for expressivity and learnability are not necessarily aligned: Languages that convey many distinctions are likely to be harder to learn than languages that encode few distinctions. Indeed, the easiest language to learn would be one in which every concept was conveyed by a single, maximally ambiguous utterance, but such a language would be inexpressive. Kirby et al. (2008), described above, used an artificial proxy for expressivity: If a participant provided the same label for two objects, only one of those labels was passed on to the next learner, thus concealing evidence that languages could be inexpressive. In another experiment in the same paper, Kirby et al. (2008) found that removing this artificial

M

Modeling Language Transmission, Fig. 1 Three models of cultural transmission. (a) shows a simple transmission chain in which a language is passed from one individual to another. (b) shows a pair of language users

who interact back and forth using a language. (c) shows a transmission chain with dyadic interaction at each generation

pressure for expressive languages produced a radically different outcome: Rather than becoming compositional, the languages are rapidly simplified, losing words and distinctions at every episode of transmission.

In a follow-up series of computer models and experiments, Kirby et al. (2015) explored the trade-off between these competing pressures, modeling the expressivity pressure in a more naturalistic way by having participants use the language they had learned in a communication game. In one condition, two speakers had to communicate back and forth about a small set of objects (Fig. 1b). After interacting for some time, the pair of language users developed a system in which each object was described by a unique, idiosyncratic word—communicatively functional but lacking compositional structure (as shown in Fig. 2b). This condition was referred to as a *closed*

group, since unlike Kirby et al. (2008) no new, naïve participants were introduced. In comparison, in the *transmission chain* condition, two participants had to communicate about the same objects, but the language was then passed on from one pair of participants to another: The language produced during communication by one pair became the input to learning for the next pair (Fig. 1c). This combination of cultural transmission to naïve learners (imposing a pressure for learnability) plus communication (favoring expressivity) led to languages with compositional structure (as shown in Fig. 2b). Communication alone, or learning alone, is not sufficient to drive the evolution of compositional structure; instead, compositionality is language’s solution to pressures requiring it to be as simple and as learnable as possible without sacrificing expressive power.

Modeling Language Transmission, Fig. 2 Results from three iterated learning experiments. (a) shows results from experiment 2 from Kirby et al. (2008). The initial input language lacks systematic structure, but after nine generations of cultural transmission, the language evolves a compositional system. (b) shows results from Kirby et al. (2015). Under the closed-group method, a holistic

language emerges; under the chain method, a compositional language emerges. (c) shows results from Carr et al. (2016). The initial input language contains no categories (each color is a different word), but after ten generations of cultural transmission, the continuous meaning space is carved up into semantic categories

Cultural Transmission Gives Rise to Semantic Categories

As described above, languages combine linguistic units, such as words, according to a compositional system. These units pick out *categories* rather than individual items or actions. For example, in English, the space of possible drinking vessels is carved up by a small number of words (e.g., *bottle*, *cup*, *flask*, *glass*, and *mug*). This categorical structure allows language users to refer to an infinite range of possible meanings using a manageable, finite number of labeled categories; this, in combination with compositional structure, is fundamental to the communicative power of human languages.

Carr et al. (2016) show how this categorical structure develops through iterated learning. Previous experiments (including Kirby et al. 2008, 2015) had participants learn and communicate about meanings drawn from a small, finite set. Carr et al. (2016) instead introduced a continuous and open-ended meaning space. Participants had to learn words for, and subsequently label, triangles that were randomly generated by selecting three vertices on a plane, such that there were effectively infinitely many objects participants could be faced with. In addition, participants were always tested on their ability to label entirely novel triangles, none of which they had seen during training. After ten generations of iterated learning using the transmission chain paradigm (Fig. 1a), category systems emerged in which this continuous space of possible triangles was carved up into around four or five categories that related primarily to their shape and size (as shown in Fig. 2c). When this experiment was adapted to include a communication game at each generation (Fig. 1c), as in Kirby et al. (2015), this combination of pressures for expressivity and learnability resulted in emergent languages that exhibited both categorical and compositional structure, thus demonstrating that both semantic categories and compositional structure can arise simultaneously out of cultural evolutionary processes.

Conclusion

Humans are the only known species with a communication system as complex as language, which must reflect unique features of our biological endowment (and thus our unique evolutionary history). Biology can provide an explanation for the basic building blocks required for language, such as the capacity for vocal learning found in other animals or the capacity and motivation to reason about the mental states and communicative intentions of others (Fitch 2010). Nevertheless, it is clear that cultural processes play a potentially important role in explaining the structure of human language. These processes can be studied in the lab, and a growing number of experiments that model what happens to languages when they are transmitted across generations have shown that at least some of the universal properties of language can be explained as a product of cultural evolution. This suggests that biological evolution should be seen as providing the basis on which cultural evolution can operate, with the detailed structural properties of language being a product of cultural evolution. Modeling language transmission therefore has an important role to play in helping us understand how language evolved.

Definition

According to the main version of moral relativism, there are no objective moral facts or properties, and instead moral facts and properties depend for their existence on certain attitudes held by individuals or groups forming moral judgments.

Introduction

This entry first provides some background about how to define moral relativism. It then reviews two different strands of the contemporary discussion of moral relativism. The first concerns the question of whether most people endorse, either implicitly or explicitly, some form of moral relativism. The second concerns the question of whether moral relativism is actually true. Here the focus will be on the influential work of Shaun Nichols, who has proposed an account of the psychology of moral judgments which he takes to provide support for moral relativism. Some problems will briefly be raised with Nichols's main argument (The material which follows is reprinted with permission from Miller 2011).

Defining Moral Relativism

Following the custom in the philosophical literature, it is common to distinguish between three

different versions of moral relativism, each of which will only be given a rough characterization here (for more detailed characterizations, see Wong 1991; Gowans 2008; Miller 2002). The first is:

Descriptive moral relativism: Some human beings have fundamentally different moral standards and values.

This is intended to be an anthropological claim about the existence and extent of the diversity of opinions about central moral issues and can be formulated in stronger and weaker varieties. Just about everyone agrees that at least a weak version of this view is correct and the debate has to do with the extent of these differences.

The second version of moral relativism can be stated as follows:

Normative moral relativism: When the moral differences of individuals or groups cannot be rationally resolved, they should not judge the moral behavior of each other nor act toward each other in such a way as to attempt to bring one side into conformity with the standards of the other.

This view is making a moral claim that people should, in effect, exhibit some degree of tolerance in such cases. And stronger and weaker varieties are on offer here as well.

Finally there is the version of moral relativism which is typically of interest to philosophers and will be the focus in what follows (for further elaboration, see Prinz 2007, Chap. 5, and Gowans 2008):

Metaethical moral relativism: There are no objective moral facts or properties, and instead moral facts and properties depend for their existence on certain attitudes held by individuals or groups forming moral judgments.

Talk of “objectivity” is notoriously hard to make precise in metaethics, but the most common approach is to formulate the notion in terms of the existence and nature of moral facts being mind independent in such a way

that they do not vary with changes in attitudes toward them (for a detailed characterization of objectivity, see Miller 2007, 2009). Someone who thought that moral facts are objective in this way would hold that, for instance, slavery is wrong regardless of whether people thought it was acceptable or not.

The “attitudes” clause gets spelled out differently by different moral relativists. These attitudes could include, for instance, people’s beliefs, emotions, values, reflective desires, or so on. A simple example of a relativist view would be one according to which something is a moral fact for a person if and only if that person believes it to be a moral fact. Hence on this view, slavery is not wrong *simpliciter* – it is wrong for Jones but right for Smith because Jones believes it is wrong while Smith believes it is right.

In what follows, discussion of “moral relativism” will refer to this metaethical version. And the focus will be on two main topics:

- (i) The psychology of folk moral judgments and whether such judgments show signs of an implicit or explicit commitment to moral relativism.
- (ii) A recent account of the psychology of moral judgments by Shaun Nichols and whether it provides support for moral relativism.

Psychological Studies of Folk Moral Judgments

Leaving aside the question of the plausibility of moral relativism for a moment, to the extent that there is one commonsense or folk view about the objectivity of morality, what might it be? Philosophers have been tempted to weigh in on this question for a number of years. For instance, Michael Smith writes that:

we seem to think moral questions have correct answers; that the correct answers are made correct by objective moral facts; that moral facts are wholly determined by circumstances; and that, by engaging in moral conversation and argument, we can discover what these objective moral facts determined by the circumstances are. (1994, p. 6)

Similarly, Russ Shafer-Landau writes that “the semantic norms that constrain truth in ethics do not (even implicitly) relativize such truth to the attitudes of the speaker or the mores of her community. We judge our moral views to be true, *simpliciter*” (2003, p. 31, emphasis his. See also Mackie 1977; Brink 1989, and Darwall 1998).

At the same time, philosophy professors are usually all too familiar with the extent to which many of their undergraduates seem to reject objective approaches to morality in favor of some kind of relativistic view (Stich and Weinberg 2001). So in order to better determine what the common-sense outlook really is, it would be nice to have some careful psychological experiments. Unfortunately, very little has been done in this area so far, although the future looks promising. Here three areas of existing research are briefly summarized.

First, quite a bit of attention has been paid to whether young children are (implicit) moral objectivists. The main approach to assessing this at the present time is to measure whether children distinguish violations of moral norms from violations of merely conventional norms on a number of different dimensions. And the results thus far have been robust. For instance, children overwhelmingly treat moral norms as more serious than conventional norms, as generalizable to other countries, as independent of an authority figure such as a teacher, and as supported with different justifications from conventional norms such as welfare considerations (for reviews see Smetana 1993 and Tisak 1995).

Shaun Nichols (2004a) accepts this work on childhood attitudes toward morality, and in a series of experiments, he examined both whether such default objectivism is still present in undergraduates and, if not, whether relativistic attitudes among students serve to undermine certain other important features of moral judgments. In his first experiment, he surveyed students about four scenarios involving conflicting opinions, two of which were a moral scenario and a flat earth scenario. For each scenario, participants were asked whether they thought one of the sides in the dispute was right and the other wrong or whether there is no fact of the matter in this case.

Six of the 46 participants gave a nonobjectivist response in the flat earth case, while of the remaining 40 subjects, 17 out of 40 gave a non-objectivist response in the moral case (10). These results suggest that by the time they reach college, a significant number of students are such that their default objectivism is defeasible, while at the same time their attitude toward morality does not depend upon a full-blown relativist view about all of reality. Similar results showed up in the remaining four studies reported by Nichols (2004a).

The second part of Nichols’ project was to examine whether those undergraduates making seemingly relativistic claims about moral disputes are still committed to other core elements of moral judgments and in particular whether they continue to distinguish between violations of moral and conventional norms. In the remaining four experiments, Nichols repeatedly found that other core features of moral judgments do still remain. In particular, nonobjectivists drew the distinction between moral versus conventional norms on the dimensions of seriousness, permissibility, justification, and dependence on authority. For instance, here is the set of questions designed to measure each of these dimensions for one of Nichols’ moral scenarios (15):

1. Was it OK for Frank to hit Ben?
2. On a scale of one to ten (with ten the highest), how bad was it for Frank to hit Ben?
3. Why was it bad for Frank to hit Ben?
4. Now what if the teacher had said before the lesson, before Frank hit Ben, that “At this school, anybody can hit someone if they want to.” Would it [be] OK for Frank to hit Ben if the teacher says he can?

Nichols’ conclusion is that, apart from their stance toward whether there is a fact of the matter in the moral cases he devised, “there is little to distinguish objectivists from nonobjectivists in any of these experiments” (23).

The most sophisticated published study of folk metaethical attitudes to date is Goodwin and Darley (2008). In their first experiment, 50 undergraduates at Princeton University participated in a

two-part study. First the experimenters had participants rate their level of agreement or disagreement with 26 statements (on a scale from 1 to 6), as well as how they would answer the following with respect to each statement (1343–4):

How would you regard the previous statement?
Circle the number.

1. True statement
2. False statement
3. An opinion or attitude

The statements were chosen so that they fell into four main categories: ethical, conventional, aesthetic/taste, and scientific.

Next, while the participant was performing an unrelated task, the experimenter chose five statements (two ethical statements and one statement from each of the other three categories) about which the participant had indicated either relatively strong agreement or disagreement. The participant was then instructed as to how to proceed next, the key part being that “None of the statements have produced 100 % agreement or disagreement. In what follows, you will be asked to indicate how you interpret disagreement with your own attitudes” (1344). For each of the five statements, the participant had to select one of the following (1344):

1. The other person is surely mistaken.
2. It is possible that neither you nor the other person is mistaken.
3. It could be that you are mistaken and the other person is correct.
4. Other.

At the end of this questionnaire, participants were asked two more questions which focused on the justification or grounds they had for their moral beliefs.

The results from Goodwin and Darley’s first experiment were striking. While subjects generally agreed to statements about the badness of robbing a bank, the goodness of anonymous donations, and to a lesser extent the permissibility of assisted death and stem cell research, their

willingness to assign truth to those statements varied dramatically: 61 %, 36 %, 8 %, and 2 %, respectively (1346). This led Goodwin and Darley to conclude that “meta-ethical judgments about the truth of ethical claims appear to be highly sensitive to the content of the claims in question, and not merely to whether the claims are generally agreeable” (1346). In addition, using the differences between the kinds of statements, Goodwin and Darley found that scientific statements were treated more objectively than moral statements, which in turn were treated as more objective than conventional statements, followed last by statements of beauty and taste (1348).

Furthermore, the two-part nature of the study allowed the experimenters to construct three categories for the beliefs in question (1345):

Fully objective: Participant regards the belief as true (or false) and regards someone who disagrees with that belief as surely mistaken.

Intermediately objective: Either (i) the participant regards the belief as true (or false) and thinks there is no need for either party to be mistaken or (ii) the participant regards the belief as an opinion and regards someone who disagrees with that belief as surely mistaken.

Least objective: Participant regards the belief as an opinion and thinks there is no need for either party to be mistaken.

For the ethical statements, 50 out of 100 responses were fully objective, 28 out of 100 were intermediately objective, and only 11 were least objective (the remaining 11 were not categorized because the participants chose “Other”) (1348). Finally, Goodwin and Darley examined the responses given to a list of four potential grounds for subjects to check as the justification for their moral beliefs. The more grounds subjects had, the more likely they were to treat moral claims objectively. And three of the four grounds ended up being predictors of moral objectivist attitudes (1349–1350).

In their second experiment, Goodwin and Darley substituted the responses of true, false, or an opinion with the question, “According to you, can there be a correct answer as to whether this

statement is true?" (1351). The results showed a similar pattern as in the first experiment, although in this case moral statements were treated just as objectively as scientific ones, and 70 % of the responses were fully objective (1352–1353).

Finally, in their third experiment, Goodwin and Darley used three short moral scenarios and otherwise employed a similar methodology to the previous experiment. However, this time at the end of the session participants had to rate the extent to which each of the four proffered justifications supported their moral belief, as well as the degree of their belief in the existence of a supreme being and their general political attitudes (1356). They found that grounding moral beliefs in a divine being predicted greater moral objectivism, and more so than political attitudes or merely having religious beliefs by themselves without them playing a role in justifying morality (1357).

Taken together, all of the studies mentioned in this section barely scratch the surface of the empirical work that is needed in this area. There need to be studies which use different adult subjects besides undergraduates and which take place outside of the USA. There need to be studies which are more sensitive to the range of metaethical options available in the literature, such as response-dependent views, expressivist views, error-theoretic views, and so forth. There need to be studies which are more careful in their accounts of what makes a moral statement, belief, position "objective," and so forth. So it is only with great hesitancy that some initial conclusions can be drawn:

- (i) Young children seem to be implicit objectivists about moral claims, and so objectivism is the default position for human beings initially.
- (ii) Our default objectivism is defeasible – many human beings exhibit a nonobjectivist attitude toward at least certain moral claims by the time they reach college.
- (iii) People tend to be neither completely objectivist nor completely nonobjectivist in their thinking; rather the degree to which they are objectivists varies in part as a function of the content of the moral statement in question.

- (iv) Those who offer some grounds for their particular moral beliefs are predicted to be more objectivist in their thinking than those who do not, especially if they ground morality in a divine being.

Clearly much further work is needed in this area.

Nichols on Moral Psychology and Moral Relativism

A separate focus of research in recent years has concerned whether metaethical moral relativism is plausible, regardless of whether people in fact accept it or not. In his 2004 book *Sentimental Rules*, Shaun Nichols has offered an influential argument that the best account of moral judgments points in the direction of moral relativism. He is not out to provide a conceptual account of moral judgments, but rather an empirically informed account of what people are doing when they make what he calls "core moral judgments." Such judgments are concerned with the moral permissibility of actions and in particular whether such actions have violated harm-based norms. Judging the wrongness of an action of hitting an innocent person purely for amusement would be a paradigm example of such a core moral judgment (2004b, p. 5).

There are two central components to Nichols' account of core moral judgments (in what follows "core" will be dropped for the sake of simplicity). The first is a person's normative theory, which is his or her body of information about what actions are wrong. And the second is an affective mechanism that is responsive to harms, where these are understood mainly as pain and suffering. The first component is used to explain why some events can be distressful and involve pain and suffering but are not considered wrong, such as natural disasters and accidents (15). The need for a second component is motivated by Nichols in various ways using cases involving psychopaths, autistic children, and disgust. For instance, psychopaths often understand both harm and conventional norms but have neither backed by an affective system, whereas normal subjects have an affective

system linked to their harm norms. Together, then, for Nichols, these two components of a normative theory and affective system give us an account of actual moral judgments as involving “sentimental rules” or “rules prohibiting actions that are independently likely to elicit strong negative effect. The set of rules or normative theory prohibits actions of a certain type, and actions of that type generate strong affective response” (18).

Nichols is clear that he takes this account to provide evidential support for a relativist position. Indeed, the conclusion of his central argument is that “[n]o action is wrong simpliciter. At best, an action is only wrong relative to a population – the population of individuals that share a certain emotional repertoire” (185). Here is the argument itself (185, emphasis his):

1. Rational creatures who lack certain emotions would not make the moral judgments that we do.
2. There is no principled basis for maintaining that these certain emotions (on which our moral judgments depend) are the *right* emotions. That is, there is no externally privileged basis for maintaining that all rational creatures *should* have the emotions.
3. [Therefore, morality is not objective.]

The opponent here is the philosopher who claims that the moral status of an action is determined “as it is in itself” and so holds that moral judgments are true in a nonrelativistic manner (184). Nichols takes his argument to show that the “common-sense commitment to objectivity is unwarranted. Given the emotional basis of moral judgment, we are not justified in our belief that morality is objective” (185).

Nichols’ main support for the first premise is that “Martians who lacked analogues of human sentiment and affection would not make the moral judgments that we do” (185). Indeed, the Martians might be aware of all the same relevant facts, but judge that torturing puppies is not morally wrong (185). Given the sentimental rules account, affect systems play a crucial role in shaping both the initial moral judgments that people make and the ones that as a culture people preserve over time.

Without those affect systems, the resulting judgments would look very different.

The second premise is really the core of Nichols’ argument. Nichols explains it more fully as follows: “there is no principled basis for maintaining that all rational creatures should have emotional responses like reactive distress and concern. There is no independent reason to think that this emotional repertoire is the right one to have” (187). Instead the burden of proof is supposed to be on the objectivist to “show that all rational creatures *should* have such emotional responses. . . . The difficulty is that it is not at all clear how to argue for such a claim” (188, emphasis his). Note, then, that Nichols does not seem to provide any actual support for premise (2), other than just taking it to be the default position and putting the burden of proof on the objectivist to justify certain emotions over others.

At this point, an objectivist about moral facts could raise at least two concerns about premise (2) and more generally about Nichols’ argument. The first is that premise (2) seems to preach to the choir. A philosopher who is already committed to some version of moral objectivism presumably has good (albeit perhaps mistaken) reasons for countenancing the existence of objective moral facts, including facts concerning the appropriateness of forming certain emotional responses rather than others. So Nichols has offered nothing by way of an argument for why the *objectivist* should accept this premise and rather just seems to be asserting that it is true.

The second concern is that it is not clear more generally why a principled basis for justifying certain emotions over others cannot be found using the agent’s own normative theory. Recall that on the sentimental rules account, the capacity for core moral judgments is constituted by an agent’s normative theory and affective system. And presumably people’s normative theories could provide them with a wealth of important reasons for why, say, emotions sensitive to distress in others are worth having whereas emotions promoting distress in other are not. One such reason, for instance, could be that relieving distress in others is important (for various reasons of its own), and beings with an emotional sensitivity

to distress in others are more reliable at detecting that distress and so are better equipped to try and relieve it. And Nichols would not be entitled to respond at this point by claiming that such reasons provided by people's normative theories are themselves arbitrary and have "no principled basis," since that would assume there are no objective reasons to begin with and so beg the very question at issue against the moral objectivist.

Nichols might reply that the above response underestimates the impact that affective systems have on normative theories. That is, he might hold that affective systems strongly influence the contents of the normative theories people hold in the first place, especially at the cultural level where they significantly impact what moral claims survive over time. Indeed, Nichols devotes an entire chapter of his book to a cultural evolutionary account of harm norms where affective systems play a central role (Nichols 2004b, Chap. 7).

Here the objectivist might make use of one of two strategies to respond. One might be to argue that the best explanation for cultural changes in harm norms over time, and by implication the best explanation for the harm norms the majority of people have today as part of their normative theories, does not involve appealing primarily to their affective systems, but rather to human beings having made progress in getting closer to the objective truth about morality. To his credit, Nichols anticipates this response and argues against it at length (159–164). At this point, the reader should judge who gets the better of that exchange.

The other strategy worth briefly mentioning is to concede that human affective systems have played a significant role in shaping their normative theories, but to note that they are only one of several factors which causally *influence* those theories, rather than being the only factor which causally *determines* them. For Nichols has not offered arguments which come anywhere close to showing that the content of people's normative theories is determined *solely* by their affective systems. Furthermore, the distinction between causal and justificatory influence is worth taking seriously, since the affective system only contributes the former in shaping an agent's normative theory, while other forces might provide both

kinds of influence. For instance, through a process of practical reasoning, an agent might come to a new moral conclusion about, for instance, the need to send money to Africa or the inconsistency between her moral views on two issues. Such processes are familiar and yet often contribute increased justificatory status to their conclusions. Or as another example, the influencing factor could be the social transmission of accumulated wisdom about moral topics through forms of testimony such as parental upbringing and education, some of which corresponds to the objective moral facts. And indeed there might be cases of such social transmission leading to a change in normative theory even in the face of resistance from the individual's affect system. To use one of Nichols' own examples, "[k]nowing that inoculations are for the best does not eliminate the discomfort one feels witnessing a child get inoculated" (155, see also Vranas 2006, 789).

Conclusion

Stepping back, the upshot of this discussion of Nichols' argument is that the sentimental rules account of people's capacity for core moral judgments might not lead to the direction of moral relativism after all, and indeed seems to be compatible in a number of respects with an objectivist metaphysic about moral facts and properties. Thus, Nichols might not be offering a clear path from moral psychology to moral relativism after all.

Modern Technology (E.G., IVF)

Hans Ivar Hanevik
Telemark Hospital Trust, Porsgrunn, Norway

Definition

In Vitro Fertilization (IVF) together with Intra Cytoplasmic Sperm Injection (ICSI) are the two major technologies applied in modern Assisted Reproduction Technology (ART).

Introduction

In 1978, the world's first “test-tube baby” was born in England (Steptoe and Edwards 1978). Her name was Louise Brown, and she was the first human born after fertilization of an oocyte by a sperm in a laboratory instead of inside the female body. Such in vitro fertilization (IVF) was at first developed primarily for treating infertility in female patients with obliterated fallopian tubes or other pathologies. Following this initial breakthrough, IVF was accompanied by other technological advances that together constitute modern assisted reproductive technologies (ART). One of these technologies is intra cytoplasmic sperm injection (ICSI). ICSI is primarily used in couples where infertility arises due to a low sperm cell count in the ejaculate. The ICSI operator holds the oocyte in a micropipette and injects it with one of the few sperm cells present under the microscope, thereby fertilizing the oocyte (Palermo et al. 1992). Some of the other technologies constituting modern assisted reproduction are the use of donor oocytes and donor sperm; the cryopreservation of sperm, oocyte, and embryos; the surgical extraction of sperm from the testicle or epididymis, in addition to uterus transplantation and the comprehensive genetic testing; and morphological screening of cells and tissues in both donors and recipients (Niederberger et al. 2018). By putting these technologies to work, assisted reproduction technology has become a common part of most modern health care systems. In several countries ART now accounts for 4–5% of babies born annually (European IVF Monitoring Consortium 2017). In 2017, it was estimated that more than six million children had been born worldwide after ART thus far.

Assisted Reproductive Technologies in Infertile Patients

Assisted reproduction's main use to date has been the treatment of infertile heterosexual couples. The diagnosis of infertility in these couples is based on WHO criteria, which states that infertility is “a disease of the reproductive system defined by the failure to achieve a clinical pregnancy after

12 months or more of regular unprotected sexual intercourse” (Zegers-Hochschild et al. 2017). Treating such couples with IVF has several possible evolutionary effects as selection pressures differ between natural and assisted reproduction (Hanevik et al. 2016). These differences in selection pressures occur at different stages in the reproductive process.

The oocyte: In natural reproduction, the ovaries in general release one oocyte each menstrual cycle. Before ovulation, this oocyte has been through a long phase of growth and development (Hsueh et al. 2015) where at least the final phases of maturation are under tight control by female reproductive hormones. In IVF, this final phase of maturation is manipulated by pharmacological means so that the number of oocytes that are available for ovulation in the ovary is higher, typically around ten. Instead of being released into the female abdomen, the mature oocytes are collected by ultrasound guided aspiration and delivered to the IVF laboratory for fertilization. This means that many of the oocytes that become fertilized in IVF would not have been so in natural reproduction. The selection pressure for timing of oocyte maturation to the naturally occurring variations in female reproductive hormones is thus less in assisted reproduction.

The sperm: After being ejaculated into the vagina in natural reproduction, the sperm has to swim through the cervix of the uterus, pass the uterine cavity and then find its way into one of the two fallopian tubes containing an oocyte that is available for fertilization. Large interspecies variation in sperm morphology is one indication that navigating the internal female genital organs, finding, and finally fertilizing an oocyte is a process with a wide scope for the effect of selection pressures. In IVF, the selection pressures are different in that the ejaculated sperm goes through one or more steps of rinsing and preparation before the sperm is either released in close proximity to the oocyte (IVF) or injected into it (ICSI). Compared to the natural situation, there is very little propulsion and navigation involved for the sperm, and in ICSI the mechanism for fertilization is also very different. Hence, the selection pressures that influence which sperm will have its

DNA represented in the next generation are systematically changed in assisted reproduction.

The embryo: The fertilized oocyte develops into an embryo that in natural reproduction travels down the fallopian tube and implants in the uterine cavity about 7 days after fertilization (Franasiak et al. 2016). In the IVF laboratory, the embryo develops in an incubator under controlled temperatures and gas concentrations, submerged in a commercially available embryo cultivation media. From the ten collected oocytes, typically one embryo will be transferred to the uterus after 1–5 days of cultivation in the lab, and surplus normally developed embryos will be cryopreserved for transfer in a later cycle. The decisions concerning which embryo to transfer and cryopreserve are taken by embryologist, who typically use criteria such as pace of development, embryo morphology and certain developmental landmarks to aid their decisions. The selection pressures for complying with algorithmically determined developmental milestones are not present in the natural situation. Compared to the natural situation, the embryo in assisted reproduction is also exposed to more mechanical stress, strong light, and exogenous chemicals, altering selection pressures.

The couple: Although controversial, a complete analysis of differences in selection pressures between natural and assisted reproduction must include a mention of the barriers that exist for couples to enter an IVF program in the first place. At least in some countries the law prevents people with serious psychiatric illness for instance to undergo assisted reproduction. Also IVF is an expensive treatment, so in many countries infertile couples with low income do not have equal chance of becoming pregnant as those infertile couples who can afford IVF. This is a systematic difference compared to the natural situation, where the chance of pregnancy does not depend on your psychiatric history or your income.

Assisted Reproduction in Fertile Patients

The use of assisted reproductive technologies is ever more common also in patients who are not

infertile by the WHO definition. This includes same sex couples, some cases of oocyte cryopreservation (so-called social freezing), and some cases of preimplantation genetic testing. Assisted reproduction in lesbian couples includes the use of donor sperm either for intrauterine insemination or for conventional IVF. Social freezing occurs when a female wishes to cryopreserve her oocytes at a young age, say when she finishes university, so that she can build a career and find a suitable husband without having to worry as much about her declining fertility if this takes longer than she expects. Assisted reproduction is also very much a part of preimplantation genetic testing, where a couple who either have or carry certain heritable diseases can make sure the “sick” gene for this disease is not transferred to their offspring. In most such cases IVF is preformed, and the resulting embryos are genetically tested to make sure only embryos without the “sick” gene in question are transferred to the uterus. These, and other, applications of assisted reproduction technologies in fertile patients may also have evolutionary implications. The case of genetically testing the embryo for instance is, in principle, applying a very specific selection pressure. However, as the evolutionary implications will vary widely depending on the specifics of the technique, analyzing their systematic difference to natural reproduction is unfruitful.

Definition

Modern theories of language represent efforts to account for the evolution, acquisition, and processing of language within an integrated framework. Such efforts acknowledge the relationship of language to sensorimotor experience, social interaction, and general cognitive constraints on information processing.

Introduction

The study of language is a diverse field that engages the applied interests of educators and speech pathologists as well as the academic interests of researchers working in wide range of disciplines including linguistics, speech and hearing sciences, psychology, biology, computer science, philosophy, sociology, and anthropology. Scholars in these different disciplines invariably conceptualize language in different ways, viewing it, e.g., as a biological attribute, a cultural trait, a set of communication skills, or a normative system of signs. This entry reviews modern theories of language that adopt the view of human language as a complex form of human behavior.

The review is organized in accordance with three perspectives considered to be complementary, as opposed to mutually exclusive: an evolutionary perspective that focuses on the origins of what are seemingly unique features of human languages; a developmental perspective that highlights the social-interactive contexts in which children acquire language as well as relationships between perception, cognition, and action in development; and a cognitive perspective that examines the processing mechanisms that determine how language use unfolds in real time.

Theories of Language Evolution and Change

Human languages seem to display many discontinuities when contrasted with the communication systems of other species. These include duality of patterning, symbolic signs, vast vocabularies, syntactic rules, and propositional structure, all of which allow for unlimited productivity in the creation of communicative signals whose meaning transcends the here and now. Modern theories of language evolution attempt to understand precursors to these discontinuous traits and what scenarios may have given rise to their emergence.

The study of the evolution of language presents extraordinary methodological challenges. The comparative method involves the study of homologous traits to uncover potential common

ancestry as well as the study of analogous traits that have emerged across different lineages to understand common selection pressures. This method has revealed strikingly few parallels between the vocal communicative repertoires of humans and their nearest relatives, the great apes, although there may be greater similarities in non-verbal forms of communication such as gesture. At the same time, the comparative method has revealed some striking similarities between humans and songbirds with respect to the imitative behaviors of juveniles and the role of social feedback in shaping immature vocalizations.

The comparative method is fraught with difficulties when trying to establish which exact traits constitute analogues or homologues in species that do not possess the faculty of language. Paleo-anthropological methods are of limited use since the fossil record does not contain clear traces of anatomical prerequisites (i.e., vocal tract structure) or of neural adaptations associated with language. Similarly, archeological methods rely on inferences about the link between the notoriously incomplete record of artifacts and the cognitive abilities involved in their production and use. Finally, the recent applications of molecular biology that try to trace the emergence of language depend on the growing, but currently still limited knowledge about the genetic underpinnings of this unique human ability. Thus, in the absence of “hard” evidence, the extant theories of language evolution and change apply conjecture or reverse engineering, or use computational modeling and experimental studies of specific selection pressures that operate during biological evolution and cultural transmission to provide proof of concept for basic principles that may underlie the emergence of language.

Evolutionary theories of language often differ with respect to what is regarded as the phenomenon to be explained. Drawing on de Saussure’s distinction between language as a system of signs (“*langue*”) and language as the product of the application of knowledge about this system (“*langage*” or “*parole*”), linguistic theory has upheld the conceptual distinction between competence and performance. The concept of language performance describes the behaviors

associated with language use such as the comprehension, production, and learning of linguistic signals. These behaviors and their anatomical, neural, and cognitive underpinnings, including domain-general cognitive mechanisms such as sensorimotor processing, working memory, planning, cognitive control, conceptual representations, and intentionality, have recently been termed the “Faculty of Language in the Broad Sense” (Hauser et al. 2002), and are the subject of study of the discipline of psycholinguistics with its vast arsenal of experimental and neurophysiological paradigms.

Theories of the evolution of the underpinnings of human language have been concerned with abilities like control over vocalization and gesture, vocal and gestural learning (including imitation), sharing of conceptual representations, and intention reading, which is required for the recognition of conspecifics’ behaviors as communicative signals. While there is debate as to whether language is homologous with animal vocal signaling systems like bird song or whether precursors of language may have initially arisen in the gestural modality, there is consensus that many of these abilities constitute adaptations to a variety of selection pressures that may not be related to language, but were likely to be related to social organization, mate choice, and tool use, and are the product of a gradual and continuous process of evolution by natural selection.

In contrast, language competence has been viewed as a cognitive capacity encompassing knowledge of a finite set of rules that can be used to generate an infinite number of utterances. It is this set of rules – called a Generative Grammar – which is seen as being at the heart of the human faculty for language. According to the theory of Universal Grammar, for a child to acquire the Generative Grammar of a specific language they must have innate knowledge of universal constraints that limit the types of structures that occur in human languages. Studying the psychological reality of Universal Grammar (i.e., the innate substrate for acquiring a Generative Grammar) is complicated by the fact that formal descriptions of what constitutes knowledge of grammar have changed since the 1960s: The

Standard Theory encompassed the notions of a deep structure describing the underlying logical relationships between the parts of a sentence, and a surface structure describing the specific manifestations of how those parts are assembled based on a set of transformation rules, the specification of which underwent major revisions in subsequent editions of the theory throughout the 1970s. In the 1980s, the Principles-and-Parameters Framework (aka Government and Binding Theory) viewed Universal Grammar as an innate set of principles comprising phrase-structure rules that specify hierarchical relationships (Government) and relationships of coreference (Binding) between words, and a set of parameters, i.e., values that define variability in language-specific manifestations of these principles, the specific values of which are set upon receiving input during the process of acquisition. Finally, in the 1990s, the Minimalist Program narrowed the human faculty for language down to a basic combinatorial operation, Merge, which hierarchically combines pairs of elements, consisting of a head and its complement, into a superordinate unit that inherits the properties of the head (e.g., in the phrase *big dog*, the adjective *big* serves as the dependent of *dog*, and thus modifies its meaning). Crucially, the product of Merge can subsequently combine with another element (either as dependent or head) to create a new unit (e.g., *the big dog*), thereby implementing the fundamental property of recursion considered at the core of the human “Faculty for Language in the Narrow Sense” (Hauser et al. 2002). As theories of the evolution of language predate the proposal of the concept of the “Faculty for Language in the Narrow Sense” this entry retains the term “Universal Grammar” when talking about the evolution of language competence.

Language as Product of Biological Adaptation

Theories that explain the evolution of Universal Grammar in analogy with the evolution of biological traits can be distinguished with respect to whether evolution is assumed to have taken place continuously or in discontinuous jumps. Adaptationist theories propose that Universal Grammar evolved gradually following principles

of Darwinian selection because it confers reproductive benefits by supporting language acquisition. In analogy to the evolution of the visual system, the central argument is that of complexity of design: In order for a cognitive entity as complex as Universal Grammar to evolve it must have been fine-tuned to fit its purpose through a lengthy process of continuous adaptation. As a result, humans are equipped with a set of innate, *a priori* constraints that enable them to solve the logical problem of language acquisition by allowing children to derive correct structural generalizations from limited input. Nonadaptationist theories argue that Universal Grammar has emerged fairly recently (~90–50 K ago) as the result of a chance mutation. This view draws on two lines of evidence: (a) archeological evidence for a dramatic rise in technological advancement attributable to artifacts that can be dated from 50 K years onward, and (b) evidence for a mutation in the *FOXP2* gene that occurred within the last 100 K years. However, given the exceedingly small likelihood of a complex set of constraints such as Universal Grammar arising through a chance mutation, proponents of the nonadaptationist view have suggested that the mutation affected only a minimal, core element of grammar – recursion (Hauser et al. 2002). Whether the ability to apply Merge recursively provides a sufficient advantage for the language-learning child to derive generalizations about grammatical structure continues to be debated, with some theorists providing evidence that Merge itself could be learned from the input, rather than existing as innate knowledge (Ninio 2014).

Language as Product of Cultural Transmission

Critics of the idea that Universal Grammar is a biological adaptation argue that this view is fraught with a number of fallacies: Given human dispersion and linguistic variability, it is unclear how an arbitrary set of universal rules could have evolved as an adaptation to different specific linguistic environments. Secondly, it is unclear why only innate representations of highly abstract grammatical properties should have evolved, rather than predispositions to learn other specific aspects of an ambient language such as its sound

structure or vocabulary. Finally, it is unlikely that modifications in the genotype could have caught up with the rapidly “moving target” of language which is liable to change over the course of even just a few generations.

Instead, recent theorizing about language evolution views language as a cultural trait that has evolved through cultural transmission via social interaction. Thus, it is not the human brain that has adapted to language but languages have adapted to be learnable and usable by humans (Christiansen and Chater 2016). Language is seen as a product of cumulative cultural, rather than biological, evolution, shaped by requirements to be transmissible across generations and expressive in communication. As a result, language is suited to the capacities of the human perceptual-motor system; the architecture of the cognitive mechanisms that underlie learning, memory, and information processing; the nature of mental representations and thought; and the pragmatic constraints that govern human communication.

Evidence for this view comes from agent-based computational simulations and laboratory experiments that manipulate various aspects of cultural transmission of language-like systems to determine how linguistic structure emerges at various levels. These lines of research suggest that combinatorial structure emerges in response to the need to transmit signals through noisy channels while compositional structure, *i.e.*, the consistent linking of form-based features to dimensions of meaning, emerges from the combined pressure of transmitting signals through limited capacity memory systems coupled with the need for users to be communicatively efficient.

Coevolution of Genes and Language

Gene-culture coevolution theories explore the feedback between genetic and cultural inheritance mechanisms. These theories draw on ideas from domains in which the interplay between genetic and cultural evolution in certain populations had been demonstrated, such as evolution of lactose tolerance as an adaptation to cattle farming, or of light pigmentation as an adaptation to colder climates. The central idea is that culture creates new

environments, which then exert specific selection pressures by influencing mechanisms that enable learning of ambient cultural traits. This view reconciles the traditional juxtaposition of innateness and learning. With respect to language, it implies that although the genotype determines the available learning mechanisms, their selection is governed by the structure of language that arises from the interaction of many individuals over time. This selection, in turn, leads to a weakening of the role of innate biases that shape leaning (Kirby et al. 2007). Indeed, recent modeling work has demonstrated that strong universality in behavior can emerge from weak biases through the process of cultural transmission. Thus, although the process of cultural evolution causes languages to adapt to the human cognitive system, the resultant structural properties of language select for cognitive abilities that are ever better suited to learning and processing of language. Following similar principles, the human larynx and the associated neural and cognitive control of sound vocal abilities may also have evolved in response to the pressure to produce more distinct sounds and words (Lieberman 2012). However, gene-culture coevolution theories that postulate genetic adaptations to language at the level of individual populations need to reconcile this view with the current lack of evidence for individual predispositions for acquiring specific languages, as would be evident if children adopted into different cultural and ethnic backgrounds exhibited specific difficulties in acquiring features of the languages of their adopted families.

How Is Language Learned?

Acknowledging the shift away from the nativist stance that regards language acquisition as a maturational process built on an innate blueprint for a formal generative grammar, modern theories of language development view first and second language learning as a process of skill acquisition (Christiansen and Chater 2016; Ninio 2006), wherein learners develop fluency in processing language in real time, i.e. converting input

consisting of sequences of sounds (or signs) into mental representations of speakers' communicative intentions and generating sequences of sounds or signs to express their own communicative intentions. Under this view, the fundamental context for language acquisition involves joint activities where speakers and listeners share common ground and can make reasonable inferences about their partner's communicative goals (Clark 1996; Tomasello 1999). The relationship between language learning and the social environment is reciprocal: the developing ability to use language facilitates social interaction, and social interaction constrains and guides the process of language learning.

Social Shaping

In the context of social interaction, language learning involves sustained engagement with parents, siblings, and other caregivers. Many theories include social learning as an integral component of language acquisition and consider how feedback from caregivers supports its development. From early infancy, caregivers and infants coordinate the timing of their communicative bids when engaged in face-to-face (dyadic) social interaction, using eye gaze as well as vocalization to modulate the amount and intensity of social stimulation. Such coordination of communicative effort fosters the development of a sense of connection between caregiver and infant while building a mutual awareness of doing something together. Recent experimental work demonstrates how contingent social feedback serves to promote more advanced speech-like vocalizations (i.e., canonical babbling) in prelinguistic infants (Goldstein et al. 2003). In this and similar studies, caregivers were prompted via an earpiece to affirm their infant's communicative attempts by smiling, touching them, or imitating their vocalizations, with half of the infants receiving contingent feedback (i.e., the prompts were timed to immediately follow the infant's vocalizations), while the other half received noncontingent feedback (i.e., the prompts were yoked to the timing of the vocalizations of a different infant from a previously recorded session). Across studies, the provision of contingent feedback was found to

increase both the quantity and quality of infant vocalizations, such that infants who received prompt, contingent feedback made a greater number of communicative attempts to engage their caregivers and produced more mature, canonical forms of babbling relative to the yoked controls. Similarly, in longitudinal designs, individual differences in maternal responsiveness to their infant's communicative bids have been shown to predict the timing of subsequent language milestones, including the emergence of first words, 50 words in expressive language, combinatorial speech, and talk about past events (Tamis-LeMonda et al. 2001), with maternal repetition or imitation of the child's speech proving to be the most impactful form of feedback for later developmental milestones.

Embodied Cognition as Expressed in Gesture and Speech

For infants, one of the major challenges involved in learning a language is to discern the referents of the words heard in the ambient language – a process referred to as word-to-world mapping. Caregivers play an important role in facilitating this process by talking about what the infant already has in mind; for instance, by naming objects that the infant is pointing at or holding. Most early verbs and other relational terms like *up* or *off* are acquired in contexts where the infant is involved in purposeful activity, which allow, for example, the infant to map a word such as *up* onto their efforts to be picked up. Modern theories of language have come to recognize that the semantic representations associated with linguistic forms are multimodal in nature and reflect the sensorimotor experiences of learners. Multimodal representations are one feature of embodied cognition wherein conceptual processing involves simulation or mental reenactment of previously experienced situations (Barsalou 2009). In children, as well as adults, accessing verb meanings is associated with neural activity in motor areas (frontal cortex), which varies as a function of the type of verb, e.g., “hand” verbs such as *clap* or *throw* vs. “leg” verbs such as *run* or *chase*, with self-generated action seeming to play a key role in the development of these neural signatures of

sensorimotor activity during verb acquisition (James and Swain 2011).

Notably, infants are learning the meanings of words at the same time as they are acquiring a wide range of communicative gestures, many of which may be viewed as forms of simulated action, as when the child puts their hands over their heads as a request to be picked up (Tomasello 1999). Young children's gestures seem to convey their thoughts when they are at the cusp of acquiring a new skill (Goldin-Meadow 2009). These gestures provide crucial information to caregivers about what their infant has in mind (i.e., what are the infant's communicative intentions), which facilitates caregivers' provision of relevant input to aid word-to-world mapping. Infants often acquire corresponding gestures prior to learning verbs like *wave*, *sleep*, or *drink*, with the word subsequently mapped onto the gesture as a component of its meaning. Gestures also seem to play a key role in young children's acquisition of combinatorial speech, as infants first combine single words with familiar gestures (e.g., pointing at a cookie while saying *more*) prior to combining two words into a single utterance (e.g., saying *more cookie*). Deictic gestures (e.g., pointing at something), in particular, may be important for the child's acquisition of a general combinatorial operation like Merge, by serving as variable expressions (i.e., with meanings corresponding to pronouns like *it* or *that*) that change in meaning depending on the context of use. Thus, learning to point as a form of request at a multitude of objects (e.g., cookies, milk, out-of-reach toys) paves the way for the child to acquire corresponding phrases such as “get it” which exemplify the situational meanings and flexible utility of linguistic expressions.

Bootstrapping in Complex Dynamical Systems

In order to process incoming information language learners need to rapidly incorporate this information into existing representations. A number of theories provide accounts for how representations of the hierarchical structure of language can be built up incrementally from the input. The evidence suggests that from the

very first moments of contact with language in utero, infants become attuned to the statistical regularities associated with the duration of vowels and consonants and the resulting rhythm of the language (Mehler et al. 1988). During infancy, sensitivity to prosodic characteristics, i.e. intonational and rhythmical patterns, provides a rich source of information that facilitates discovery of the underlying grammatical structure of a language because prosodic and syntactic structures tend to be aligned to a considerable degree (Morgan and Demuth 1996). The process of discovering the sound patterns and structures of the ambient language is aided by the fact that child-directed speech often exaggerates phonetic and prosodic characteristics in ways that support the discriminability of phonemes (i.e., meaning-bearing speech sounds) and discovery of higher order units, such as words, recurrent morphemes, and phrasal constituents. Thus, the rich input supports online bootstrapping of linguistic structure at multiple levels. More generally, the notion of bootstrapping implies that as children acquire aspects of language, such as the meanings of concrete nouns that can be learned ostensively through a process of word-to-world mapping (e.g., pointing at an object to elicit its name), they can make use of familiar forms (i.e., what they have already learned) to aid them in learning unfamiliar and more abstract words and structures (Gleitman et al. 2005).

The notion of bootstrapping and learning as being supported by affordances of the environment extends beyond language input: Language development is grounded in the infant's sensorimotor experience, which undergoes abrupt transitions as infants develop motor skills over the first year of life. Recent work has explored how the transition from crawling to walking provides infants with new ways of sharing their interest in objects with others, which in turn may alter the communicative dynamics of caregiver-child interaction. In a study focusing on 13-month-olds, where half of the infants were already walking and half were still crawling (Karasik et al. 2011), walkers more often carried objects to their mothers, shared their interest in objects from a distance, and communicated their interest in

sharing an object while in motion. The observed differences in how walkers and crawlers shared objects with others had unexpected consequences for communicative development by influencing how the mothers perceived their infants' communicative intentions. Mothers responded differentially to the moving bids (favored by the walkers) in comparison to the stationary bids (favored by the crawlers) by producing more advanced action directives, such as "open it," when the child offered or showed them the object while in transit. These findings suggest that developmental changes in one domain (i.e., motor development) can yield cascading effects on development in a seemingly unrelated domain (i.e., language development) by altering parent-child conversational patterns, which, in turn, enriches the input to the language-learning child.

Usage-Based Learning

In the face of decay, incoming linguistic information needs to be processed rapidly by the learner. As a result, learning is based on local contingencies processed in small chunks rather than on surveying and generalizing over large corpora of previously encountered input. This assumption is built into a number of theoretical frameworks that focus on the dynamics of language usage, chunk and pattern extraction, categorization and generalization, and change over time; these include connectionist, emergentist, and usage-based approaches to language and development. According to these approaches, infants and toddlers learn language in a piecemeal fashion, starting out by acquiring words and phrasal patterns that are relevant to their daily routines, such as mealtime or book reading, using mutually understood activities and predictable communicative formats to make sense of the accompanying language. Through a process of cross-situational statistical learning, young children hone in on the meanings of words and at the same time become sensitive to the unique ways that individual words co-occur with other words, including their frequency of occurrence in different syntactic and situational contexts. Acquisition of item-specific co-occurrence statistics supports priming, wherein the processing of linguistic structure

becomes more fluent and efficient as a function of item and pattern familiarity. Storage of pre-compiled units or chunks of language incurs further benefits by allowing the child to make incremental predictions about what comes next when processing language in real time. By emphasizing statistical learning of distributional information, which includes monitoring how often different lexical items appear in different grammatical constructions, these approaches provide dynamic accounts of how children go from being fairly conservative learners to making the sorts of constrained generalizations that allow sophisticated language users to achieve the unlimited expressive potential of human language.

How Is Language Used?

Language is transient. Humans are able to comprehend language at a rate of about 20 phonemes per second despite the fact that the ability to differentiate nonlinguistic sounds is limited to about 1.5 per second. This implies that current input is rapidly overwritten by new input, urging immediate processing – a phenomenon referred to as the *Now-or-Never bottleneck* (Christiansen and Chater 2016). Similarly, the planning of action sequences, such as those required for speech production, is temporally constrained as planning of long sequences far in advance is hampered by interference and forgetting. These constraints are reflected in a number of basic features of processing systems, which are discussed below. These basic features of the architecture of the language processing system – viewed as consisting of a series of subprocesses that operate in a cascaded manner utilizing different types of information in an interactive manner in order to interpret and even predict upcoming input – are thought to govern both language comprehension and language production, although controversy persists about the extent to which the two systems share parts of their architecture and underlying neural substrate (Pickering and Garrod 2013). Crucially, the principles that underlie language processing and communicative interaction may be shared with processing architectures in a

number of other domains such as visual perception, action planning, or social cognition, rather than being unique to language.

Levels of Processing

Theories of language processing postulate components or stages that deal with different types of information in the signal, such as phonological, prosodic, lexical, morphological, syntactic, semantic, and pragmatic information. Early theories were heavily influenced by the idea of modularity of processing of different types of information (Fodor 1983). As a consequence, language processing was assumed to handle different types of information in several stages assembled in a strictly sequential and independent way, such that information processed at later stages could not influence processing at earlier stages. For example, the process of utterance or sentence comprehension was conceived of as parsing the input to uncover the underlying syntactic structure, formalized as a phrase-structure grammar. Parsing was viewed as incorporating the input into a syntactic tree in incremental fashion following a set of heuristics that minimized memory load by limiting the number of higher-order syntactic units that could be assembled at any given point in time. Semantic processing was postulated to be subsequent to the identification of syntactic structure, and semantic information could not be admitted for resolving processing uncertainties at earlier stages. The idea that processing proceeds from lower to higher levels in strictly sequential fashion was also echoed in early theories of language production where information was propagated sequentially in the reverse direction.

Incremental Cascaded Processing

More recent theories acknowledge that the rapidly fading signal necessitates efficient conversion of sensorimotor input into higher-level representations. This constraint is reflected in the feature of incremental processing, whereby small chunks of input cycle through the various processing stages so that earlier chunks are already integrated with higher-level information while lower-level information is still being processed to create later chunks. For example, studies of speech

shadowing have shown that speakers routinely correct errors in the speech stream, which suggests that spoken word recognition proceeds extremely rapidly based on partial input allowing higher-level lexical information to be used to assemble articulatory commands while lower-level phonological information is still being processed. For larger segments of input, like utterances and sentences, the idea of incremental processing was first introduced by the two-stage sausage machine model (Frazier and Fodor 1978), which proposed that incoming words first get chunked into syntactic phrases, which are then incrementally incorporated into a syntactic representation. Modern theories assume a massively cascaded architecture according to which the processor chunks the incoming input and immediately passes the information on to higher levels of information processing while at the same time continuing to process lower-level information in the subsequent input (Christiansen and Chater 2016).

An incremental cascaded architecture has also been proposed in speech production theories, which show – based on empirical findings from picture-word interference tasks – that higher-level structure, e.g. the semantic and syntactic structure of an utterance, is constructed incrementally and on the fly. Recent evidence from syntactic priming suggests that speech planning involves a syntactic planning phase that is independent from semantic content and phonological form and liable to reusing the structure of recently encountered input (e.g. Pickering and Branigan 1998). The idea of purely syntactic representations derives from earlier theories of speech production, which postulated separate syntactic representations of words called *lemmas* (in contrast to *lexemes* carrying phonological information). In the production of continuous speech, syntactic planning spans somewhat longer time windows than planning at lower levels, e.g. planning of prosodic structure, which, in turn, is planned further ahead than syllabic and phonological structure, attesting to the cascaded nature of the process. Controversy exists with respect to the size of the preplanned components, and the extent to which preparation of multiple components involves parallel processing.

Interactive Processing

In comprehension, incremental chunk-by-chunk processing runs into problems when correct interpretation of current input depends on information that only becomes available in the yet-to-be-processed input. At the level of identifying individual words, ambiguities can arise from distortions in the acoustic signal (i.e., noisy input), from a lack of one-to-one correspondence between the signal and the intended word form (i.e., polysemy and homonymy), or from competition from phonologically related words with similar onsets (i.e., words in a cohort such as *carbon*, *carton*, *carpenter*, etc.). Often, such uncertainties in spoken word recognition cannot be alleviated through bottom-up processing, thus requiring the listener to make inferences about the intended word based on probabilistic contextual cues. Empirical evidence shows that the lexical status of the ambiguous word as well as the coarticulatory properties of the surrounding sounds can affect the sensitivity of early sensory processing of speech sounds, suggesting that the processing system is interactive. In many instances of noisy input, interactive processing includes the use of crossmodal sensory integration (e.g., lip reading) to facilitate rapid restoration of missing/distorted phonemes (Massaro 1987). Moreover, higher-level information can influence processing retrospectively; for example, accessing lexical knowledge about a given word can influence interpretation of ambiguous phonological information that was encountered within that word, for example, a sound with a voice onset time between /d/ and /t/ is perceived as /t/ at the end of /pi/ because /pit/ is a word but /pid/ is not. Such effects have successfully been implemented in connectionist word recognition models such as TRACE (McClelland and Elman 1986).

Ambiguities can also arise in sentence processing. For example, in so-called garden-path sentences, such as *The horse raced past the barn fell* or *Put the frog on the napkin in the box*, listeners may be led down the garden path to form an incorrect interpretation of the sentence. This occurs when information early in the sentence, e.g., the past participle *raced*, is misunderstood, e.g., taken to be the main verb in the

sentence as opposed to a modifier of *horse* (part of a reduced relative clause). Early sequential theories postulated that the processing system commits itself deterministically to just one interpretation using a set of processing heuristics. According to these theories, listeners will subsequently revise their interpretations of sentences only if incompatible information is encountered, with reanalysis manifesting itself in processing cost measurable by error rates, reaction times or electrophysiological markers indicating processing of unexpected information. Crucially, the process of reanalysis is thought to be triggered by various types of information that are independent of syntactic structure, such as semantics, discourse structure, pragmatic inference, and/or real-world knowledge. Reanalysis may not be fully available to young children who show minimal evidence of revising incorrect interpretations of temporarily ambiguous sentences, like the examples given above (Trueswell et al. 1999).

In contrast, interactive constraint-satisfaction theories (MacDonald et al. 1994) permit the processing system to maintain several alternative interpretations of a sentence in parallel, with viable interpretations continuously constrained by multiple information sources (see list above for sources of information guiding the process of reanalysis), thereby limiting the need for second-pass revisions under most circumstances. Thus, a phrase such as *The witness interrogated...* is much less likely to be interpreted as a noun + main verb than the similarly structured phrase *The horse raced...* because a variety of factors, including frequency of use, encourage the listener to interpret the noun phrase *The witness* to be the object of the verb *interrogated*. Such probabilistic information may be obtained through statistical learning of co-occurrence patterns in the input (see subsection above on Usage-Based Learning), although other information may reside in the context of the specific communicative episode. There remains controversy with respect to the amount of information that can be retained in a memory buffer before an ambiguity must be resolved and the types of information that can be considered at various processing stages. It has been suggested that listeners often do not consult all available

sources of information in processing a sentence, but rather engage in satisficing to generate “good-enough” representations that minimize effort and processing cost (Ferreira et al. 2002).

Top-Down Processing

As indicated, higher-level information can be used to resolve uncertainty at lower levels of processing either by aiding in the selection of the correct interpretation among the various alternatives activated by bottom-up processing, or by selectively preactivating just one compatible interpretation at the exclusion of others, even though such top-down processing could lead to misinterpretation of upcoming input. Controversy has arisen about whether context-based facilitation of bottom-up processing reflects top-down processing, or whether it just arises from priming, i.e. from the spreading of lingering, yet rapidly decaying, activation of already-processed input at lower levels of representation. This controversy is of greater relevance in sentence processing than in word processing, where top-down processing has been demonstrated by predictive eye movements in the visual-world paradigm, for example, when participants perform eye movements toward objects predicted by the previous context (Altmann and Kamide 1999). In contrast, in studies of sentence processing there is less agreement on whether high-level information can influence bottom-up processing of lower-level information directly, or whether it merely aids in selection of different alternatives constructed by lower-level processing. One reason for the difference between word and sentence processing lies in the length of the time windows necessary for processing relevant information. Whereas top-down influences on word recognition occur within a relatively short time window (not overly taxing on memory and processing resources), top-down influences on sentence processing require a much longer time window for morphological, syntactic, and semantic processing. However, recent neurophysiological evidence supports the idea of top-down effects in sentence processing: differences in low-frequency oscillatory neural activity indicate reciprocal entrainment of cortical networks associated with lower and higher-level information

processing prior to point at which disambiguating input is encountered (Lewis and Bastiaansen 2015).

Predictive Processing

By definition, introducing top-down influences into a cascaded processing system makes processing predictive. Prediction safeguards the system against loss of information in the input due to noise in the transmission channel and in neural processing. The exact nature of how prediction operates is currently the subject of considerable debate. In its minimal sense, prediction implies that contextual effects from other types of information can influence the state of the processing system before further bottom-up processing has taken place. Theories differ with respect to whether prediction operates in a deterministic or probabilistic manner. As described above, early theories were deterministic in that they proposed top-down processing to favor one possible interpretation, typically the strongest contender of all possible interpretations, which was either the simplest in terms of memory load or the most frequent. In cases of mismatch between the predicted and incoming input (as in the case of garden-path sentences), the processing system had to reanalyze the input to identify the alternative with the greatest plausibility. Recent evidence, however, favors graded prediction effects, which are determined by the surprisal of a given continuation, i.e. by the amount of new information that would potentially be gained by processing this particular alternative: the higher the surprisal, the higher the processing cost. Thus, recent theories propose that several alternatives, each weighted by a certain strength of belief, can predictively be computed and remain active in the processing system until a resolution has been achieved. The process of resolution is proposed to follow an “ideal” or “rational observer” model, which engages in incremental belief updating using Bayesian inference to change an existing prior distribution of probabilities for the various interpretation alternatives to a new posterior probability distribution, which, in turn, becomes the prior distribution for the next processing cycle. Modern theories are trying to illuminate how people trade off the benefits and costs associated with

predictive preactivation in different domains of language processing.

Communicative Interaction

Traditional theories of language processing were developed to account for empirical findings of laboratory studies involving single speakers or listeners subjected to sophisticated manipulations of language input in the absence of a conversational partner. Recent theorizing has increasingly shifted the focus toward understanding how humans use language to engage cooperatively with others (Clark 1996) and how the production and comprehension systems of interlocutors interact when taking turns in conversation (Pickering and Garrod 2013). Modern theories of referential communication attempt to apply principles of interactive processing and Bayesian prediction to explore how speaker intent can be encoded and recovered efficiently in the face of pragmatic constraints on the amount of information conveyed in speech (Frank and Goodman 2012). Processing principles derived from comprehension and production research can also be applied to model the communicative interaction itself by demonstrating how mechanisms like priming, inference, and monitoring of output lead to interactive alignment of linguistic signals at various levels of information processing, with the ultimate goal of achieving an alignment between interlocutors’ internal representations. Here, controversies persist around the question of “audience design” – under what conditions humans engage in strategic and volitional attempts to align the form of their output and adjust its informativeness in relation to the expectations, needs, and assumed mental models of different conversational partners. Furthermore, the question as to how language is embedded in, and governed by, communicative behavior in general has led to proposals about the evolutionary primacy of turn-taking behavior and its ontological independence from language (Levinson 2016).

Conclusion

Modern theories of language try to understand how language use arises from domain-general,

embodied learning and processing mechanisms operating in service of communication that takes place in richly structured social environments. Research has begun to move away from the study of language as the behavior of individuals to consider how it arises as a cooperative enterprise within social groups ranging in size from dyads to global communities. Contemporary theories of language are informed by powerful mathematical and computational models, big-data approaches to the analysis of natural language corpora, neurophysiological methods, and traditional laboratory experiments, designed to illuminate social as well as cognitive mechanisms underpinning language learning and processing. These complementary methodologies have the potential to offer new insights for understanding language as an emergent property of the biological substrate of individuals engaged in complex, hierarchical social interactions.

Modularity of Mind

Shameem Fatima
COMSATS University Islamabad,
Lahore, Pakistan

Synonyms

[Cognitive modularity](#); [Domain specificity](#); [Mental modularity](#); [Mind modules](#)

Definition

A cognitive system is composed of neural structures and mental processes that to some appreciable extent are distinct, localized with neural architecture, and domain specific. More simply, modularity of mind means functionally specialized mental systems.

M

Introduction

The functional architecture of the mind can be traced back in history into two competing views: (i) the **horizontal view** refers to mental processes as interactions between mental faculties which are not domain specific such as perception, memory, judgment, etc., and (ii) the **vertical view** explains that mental faculties are domain specific, computationally independent, genetically programmed, and linked with localized neural structures. The latter view dates back to the nineteenth century presented by F.J. Gall, who contends that specific mental faculties are linked with specific brain areas.

Afterwards, in the later nineteenth century, the term *modularity* has entered in the *Dictionary*

of *Cognitive Sciences* following the book *The Modularity of Mind* (Fodor 1983). Since then, Fodor has been known to be the major proponent of cognitive modularity. However, Fodor's approach to modularity of mind is a modest approach explaining that mind's input systems are modular while central cognitive systems are not modular. Since Fodor's work, conceptual landscape of modularity has improved radically. Later on, skeptics of Fodor have adopted a less rigorous but a massive approach to modularity by arguing that the mental architecture is more pervasively modular. Recently, the concept of modularity has been extended in related disciplines including epistemology, language, philosophy of science, and ethics.

Fodor's Modularity of Mind

Fodor's approach to modularity of mind is somewhat a modest approach, but the criteria of modularity are very stringent. Jerry Fodor draws his idea of modularity of mind from Chomsky's idea of language acquisition device as well as from other works on linguistics and optical illusions. His approach offers two components: the first component offers that mind's input systems mainly involving language and memory are modular. The second component, however, negates modularity in central cognitive systems involving belief fixation and practical reasoning.

In Fodor's (1983) view, input systems are mind's computational systems through which the world is presented to mind by processing of sensory transducers. A sensory transducer presents the sensory information to the mind into a computationally usable form where input processing draws hypotheses about the object to pass it on to central systems for further processing and in turn for the formation of behavior. Fodor asserts that modularity of input processes means that these input systems have a group of psychologically interesting properties to be recognized as modules, which are listed as nine features of modularity in his classic book (Fodor 1983). He asserts that any system to be recognized as modular must fulfill these features, but not all at

the same time, to some interesting extent. These features in original order are:

- (i) Domain specificity: modules are specialized which function in response to certain kinds of inputs.
- (ii) Mandatory operation.
- (iii) Limited central accessibility.
- (iv) Fast processing speed.
- (v) Informational encapsulation.
- (vi) Shallow outputs: generating a very simple output.
- (vii) Obligatory firing: mandatory processing.
- (viii) Characteristic ontogeny.
- (ix) Fixed neural architecture.

Among all these nine features, "information encapsulation" is the most fundamental of modularity to Fodor as well as to Pylyshyn (1999), who argues that information encapsulation among nine features stands out as being the actual characteristic of a module. To Pylyshyn, encapsulation makes a module encapsulated from both cognitive influence and from cognitive access. One best example of this is the Müller-Lyer illusion which is not even influenced/corrected by the conscious awareness of the illusion.

Although Fodor claimed for lower cognitive systems to be modular, he argued that higher-level central cognitive systems are not modular. As the central cognitive processes are involved in practical reasoning through non-demonstrative inferences, which cannot be understood in an informationally encapsulated system, central processes cannot be modular. He further argues that central cognitive processes are meant for belief fixation which is isotropic. As isotropic processes cannot be informationally encapsulated while modular systems are encapsulated, hence, belief fixation and central systems cannot be modular.

Critically, and even in Fodor's view, the non-modular characteristic of central systems is a serious threat to existence of cognitive science. He supports his pessimistic view of non-modular central system in two ways: First, global and isotropic systems do not seem to relate to specific neural structures, thereby making them a dubious

subject of neurocognitive science; second, global systems are resilient to computational processes, further making them a hopeless subject for psychological study.

Criticisms/Challenges: Skepticism to Fodor's Proposal of Modularity of Mind

Skeptics of modular input systems have challenged information encapsulation and cognitive impenetrability of linguistic and perceptual processes (e.g., Marslen-Wilson and Tyler 1987; McCauley and Henrich 2006). Among them, Prinz (2006) has widely challenged the modularity and encapsulation of perceptual systems by presenting a dual argument: First, likely cross-modal effects in speech perception argue against encapsulation, the best example of which is McGurk effect (McGurk and Macdonald 1976). Second, top-down effects on linguistics and perception processes also argue against encapsulation and cognitive impenetrability. Top-down effects are evident in scientific studies of phoneme restoration effects where subjects fill in the missing phoneme in spoken language. Furthermore, cognitive psychologists contend that lower-level cognitive processes are continuous with higher-level cognitive processes pointing them to be inferential and informationally penetrable.

Massive Modularity

Competing viewpoints on modularity of mind have come from evolutionary psychology whose proponents adopt a less stringent definition of modularity but at the same time claim that mind is more extensively modular from peripheral lower cognitive processes to higher cognitive processes. This view proposes that modules are mental processing units which have evolved over time as a consequence of evolutionary selection. Their proponents suggest that mind is comprised of genetically determined domain-specific computational modules, which are planned to solve particular evolutionary problems, with specific

neural circuits solving specific adaptive problems (Cosmides and Tooby 1994).

Contemporary theorists including Sperber (2002) and Carruthers (2006) assert that the mental architecture is modular from lower cognitive functions to higher cognitive functions including decision-making, reasoning, problem-solving, planning, etc. The theory is sometimes known as massive modularity. Notably, post-Fodorians adopt a less rigorous operative definition of modularity. To Carruthers (2006), "module" means isolated function-specific processing systems, which are domain specific and associated with specific neural architecture, and is likely to have inaccessible inner operations. He excluded many of Fodor's proposed modular features from the operative notion of modularity including encapsulation, shallow output, fast processing speed, transducer computation, and innateness. Importantly, proponents of massive modularity were mainly concerned with modularity of central cognitive systems while being least concerned with modularity at lower-level input systems. Originally spoken and promoted by proponents of evolutionary psychology (Sperber 2002; Cosmides and Tooby 1994; Barrett 2005), the massive modularity view has attained its most comprehensive defense at the hands of Carruthers (2006).

Conclusions

In the late nineteenth century, the term *modularity* has entered in the *Dictionary of Cognitive Sciences* following Fodor's book *The Modularity of Mind* (1983). Since then, Fodor has been known to be the major proponent of cognitive modularity. Fodor's approach to modularity of mind is a modest approach explaining that mind's input systems are modular while central cognitive systems are not modular. However, he adopts a very rigorous definition of modularity with nine rigorous features. Later on evolutionary psychologists and proponents of massive modularity theory adopt a less stringent criteria of modularity while arguing that mind is modular through and through from lower-level input systems up to higher cognitive processes. They propose that mind is comprised of functionally

specialized modules which are domain specific, genetically determined, and associated with specific neural structures and which are designed to solve specific evolutionary and adaptation problems.

Definition

Suicide terrorism as directed kin altruism might entail monetary benefits to the kin of the attacker.

Introduction

One tactic used by terror organizations to recruit combatants is to offer monetary compensation to the family members following the completion of a successful attack. Reciprocal altruism and kin selection might factor into decision-making concerning whether one should undertake a suicide mission.

Theoretical Overview: Monetary Benefits to Kin

From an evolutionary perspective, providing monetary compensation to the family members

of suicide attackers might play a role in the cost-benefit analysis of suicide terrorism since genetic kin would ostensibly receive benefits that could enhance their fitness. According to Human Rights Watch (2002), Hamas paid the families of suicide attackers between \$10,000 and \$25,000, and as cited in Bloom (2004) also provided services such as medical care (Blackwell 2006). This represents a form of reciprocal altruism (Trivers 1971) in regards to the exchange between the attacker and the terror organization as well as a form of kin altruism (Hamilton 1963). While there is some evidence that benefits to kin could outweigh the costs of a suicide attack (Blackwell 2006), the evidence is limited that monetary compensation sufficiently outweighs for the total reproductive failure that typically accompanies suicide terrorism.

Problematically, suicide terrorists and their families are often not impoverished. Rather, they tend to be better off financially on average than the general populations from which they come (Krueger and Malečková 2003). Nevertheless, suicide terrorism corresponds to rises in national poverty levels, and suicide attackers tend to come from poorer regions (Pedahzur et al. 2003). In sum, suicide terrorists come from political regions that are relatively impoverished, but the combatants themselves and their families tend to be wealthier than their neighbors.

A preliminary model tested by Blackwell (2006) demonstrated that suicide terrorism can benefit, specifically, close siblings. Using the Palestinian conflict, Blackwell found that suicide terrorists with middle class backgrounds and large families with many male siblings in particular could benefit their families most.

Conclusion

Thus far, the models demonstrating that the potential benefits of suicide attack to kin outweigh the costs to the attacker are preliminary and might not take all of the critical variables into account. Nevertheless, this is fertile ground for future research.

Definition

Monoamine oxidase is an enzyme that initiates the oxidation of monoamines, which includes neurotransmitters.

Antisocial behavior refers to behaviors or actions that are conflict with societal norms and standards such as conduct.

Introduction

Evolutionary psychology helps to describe how a human may develop biological advantages to antisocial behavior in some circumstances. In a society that values altruism and working together, antisocial traits such as robbery and sexual coercion can prosper in a small minority of people as an alternative means of survival to altruism. Natural selection does not necessarily prioritize overall wellbeing as much as it does general survival fitness. Antisocial behavior (like much of psychopathology) has genetic roots (Del Giudice and Ellis 2016). For antisocial behavior the driving force behind procreation and passing genetic information down to offspring is to dominate other people in an aggressive manner by inciting violence and breaking established rules (stealing of resources), giving them an edge over their more docile and cooperative competition (Woo and

Keatinge 2016). Buss (2009) suggests that evolution in the field of psychology is how people acclimate to their environment, survive, and develop children of their own to pass on their genes to their children.

Environment, Evolution, and Antisocial Behavior

People who exhibit antisocial behavior tend to be charming and have the ability to swindle required resources – like food and money – from other people who earned it by growing crops or trading goods. Deceit is their primary survival skill (Woo and Keatinge 2016). Buss states that particularly in the field of clinical psychology, people may not biologically advance properly causing a disturbance in their overall development – this may allow for maladaptive development strategies to flourish – like antisocial behavior. In the environment, extreme poverty may perpetuate the development of antisocial traits, where many individuals may view conning other people as a way to thrive. A hallmark of antisocial behavior is inconsideration of the rights of other people. People with antisocial behavior may thrive in their development by mating with each other, allowing them to flourish in small enclaves. When the couple has children, they may neglect and abuse their children, perpetuating the cycle of antisocial behavior (Saddock et al. 2015). Eventually, their high-octane lifestyle may come to a halt when they age and vitality begins to diminish (Woo and Keatinge 2016). If one is successful in reproduction they will successfully pass on their genetic information to their offspring – like their monoamine oxidase levels.

What are MAOs?

Monoamine oxidase (MAO) are enzymes that destroy additional neurotransmitters produced in the human body (Carlson and Birkett 2017). MAO-A genes impact three different neurotransmitters: dopamine, norepinephrine, and serotonin

(Godar et al. 2016). Initially, psychiatrists prescribed MAO's to treat major depressive disorder. This would help to improve the moods of patients (Breedlove and Watson 2013). It can also be used to treat social anxiety disorder, while MAO-B can alternatively be used to treat Parkinson's disorder. MAO inhibitors can be rather effective in treating patients; often patients report feeling very well after taking them. However, they are not used as frequently because they can be toxic if taken with foods that have high levels of tyramine, such as cheese (Lovatt 2011). MAO-B impacts mostly dopamine and can also have anticholinergic effects, blocking acetylcholine flow (Carlson and Birkett 2017).

Monoamine oxidase A (MAO-A) is a gene located in the X chromosome, given that MAO-A has a clear genetic link between its level of activation (particularly in males) and violent behavior. Males who participated in a study by Galina and colleagues (2016) had lower rates of MAO-A levels, which is linked to impulsive behavior which may make them more likely to commit violent crimes. Although different strains of MAO's exist to preserve antisocial behavior, for example, MAO-A appears to be the most commonly researched when it comes to antisocial behavior. Lower levels of MAO-A have been found in those who involve themselves in antisocial behavior. Males may be trying to compensate for their low levels of MAO-A by engaging in risky behavior that is highly rewarding, such as unprotected sex, violence, and substance use (Galán et al. 2017).

Given its location in the X chromosome, it is most prevalent to males. In biology, dichotomous "sex" is determined by the X chromosome in males and females. Males have an X and a Y chromosome, while females have two X chromosomes. The two X chromosomes often cancel genetic defects making maladaptive genes more prominent in males. The second X chromosome in females negates most genetic deformities (Xu et al. 2017). Sjöberg found that in prison populations a transcription of the 3-repeat (short) allele means a decreased MAO-A rate and as a result a potentially increased serotonin in the synapse, which may increase the chance that one

may develop aggression in antisocial behavior (Sjöberg et al. 2008).

Environmental Interactions of MAOs and ASPD Development in Males

Low activating MAO-A genes may be partially responsible for weakened verbal functioning in those with ASPD. This could help explain the higher rates of ASPD in males (Jackson and Beaver 2015). In a high-stress environment, low levels of serotonin may influence one's impulse behavior, making them more likely to act without thinking (Sadeh et al. 2013), requiring more frequent behavioral rewards to keep satisfy the individual. Those with decreased levels of MAO-A increase the chance one may be more impulsive than those with augmented levels of MAO-A (Sadeh et al. 2013). Supporting evidence by Checknita et al. (2015) found that those with ASPD and those who have low levels of MAO had higher levels of serotonin. Those with ASPD likely have parents or other initial relatives with the diagnosis, indicating a biological link (American Psychiatric Association 2013). A variety of studies examining the relationship of MAO and antisocial behavior looked at how abuse impacted MAO and antisocial behavior.

Galán et al. (2017) investigated MAO-A and antisocial behavior in a longitudinal study. They found that males who suffered extensive abuse and had lower MAO-A activation were more likely to be involved in criminal behavior such as a history of violent arrests. The same results were not found among males with high activation of MAO-A. Maltreatment as a child also increased the risk of antisocial behavior; however, mistreatment would have to occur before the age of 12 to increase ASPD risk (Haberstick et al. 2014). MAO levels in children are unlikely to be a solid predictor for antisocial behavior. Children with low MAO levels did not exhibit antisocial behavior more than individuals with increased MAO levels.

Derringer et al. (2010) suggests that conduct disorder and antisocial behavior are more extreme in those with lower MAO-A level activation. MAO-A levels alone are not strong enough to predict antisocial behavior among young males.

Males with lower MAO levels had higher rates of violent outbursts than those with high MAO levels. High MAO levels do not increase the chance that one will develop ASPD (Haberstick et al. 2014). Sjöberg et al. (2008) suggest that MAO-A genotype may interact with testosterone in predicting antisocial spectrum behavior. Researchers did not find a direct association between the lower activity variant and aggressive behavior (Sjöberg et al. 2008). In a study conducted on male inmates, researchers found a correlation between levels of MAO-A and violence. Those with an extremely low functioning of MAO-A gene had a higher level of violent outbursts (Tiihonen et al. 2015). Parental neglect damages the amygdala, making emotional processing more difficult and further developing the chances that one may develop ASPD. The amygdala aids in emotional processing. A difficulty or absence of emotional processing is a chief symptom of ASPD (Byrd and Manuck 2014).

Adolescents and Children

Adolescents with ASPD and low MAO-A levels appear to be relatively extraverted, according to one study that used the Minnesota Multiphasic Personality Inventory who wanted to see if MAO-A potentially influenced personality development (Xu et al. 2017). Jackson and Beaver (2015) examined whether nutrition would activate MAO-A genes, impacting antisocial traits. Diet did not explicitly influence MAO-A activation in participants; however, adolescents who had an active MAO-A gene and consumed more fast-food than vegetables showed more antisocial traits during adulthood. Correlational studies have found that diets missing certain nutritional elements such as vitamin C and calcium may cause children to insufficiently develop verbal skills at the same rate as those who were given a proper diet, influencing the development of antisocial traits (Jackson and Beaver 2015). Testosterone levels in children may be a much better predictor of aggressiveness. In a positive environment, low MAO levels may be protective of future development (Nilsson et al. 2018).

Brain Scans in Males

An MRI study was conducted on a group of males with antisocial personality disorder (ASPD). Researchers looked at MAO-A activation in control participants and those diagnosed ASPD. Participants with decreased MAO-A activity were more likely to have an ASPD diagnosis and had lower levels of right basolateral nucleus functioning than healthy participants (Kolla et al. 2017; Kolla and Houle 2019). The prefrontal cortex impacts control and allows humans to solve puzzles. A brain scan was conducted on ASPD patients and non-ASPD patients and found that dorsal lateral prefrontal cortex activity was weakened among those with ASPD. When compared to non-ASPD males who were not incarcerated, incarcerated males with a low functioning MAO-A gene had lower orbital frontal cortexes and ventral striatum functioning. It is possible that because of the lower functioning orbital frontal cortex and ventral stratum, individuals with ASPD were more impulsive and aggressive (Kolla et al. 2017). Kolla et al. (2015) found that impulsiveness may be impacted by a mutation of the eighth axon of the MAO-A gene. Those with the mutation were more likely to be aggressive and impulsive, important traits understanding ASPD. The same results could not be replicated when conducted on incarcerated populations with ASPD (Kolla et al. 2015).

Animal Studies

Antisocial behavior can also be present in some primates. In a meta-analysis conducted by Nilsson and colleagues (2018), they tested MAO-A levels in rhesus monkeys and found that some of the more aggressive monkeys also had lower MAO-A levels. In mice, researchers were able to induce Brunner syndrome by lowering levels of MAO-A in them. Like in humans, this would cause the mice to become riddled with an excessive amount of anger. Brunner syndrome is a genetic defect found in males that have extremely low levels of MAO-A (Godar et al. 2016).

Female Relationship of MAO's and Antisocial

Data involving MAO's and antisocial behavior is not as clear for females as it is for males. MAO levels may not be an excellent predictor of ASPD for females; however, high MAO levels may make one of more emotionally reactive which could eventually positively impact the development of ASPD. For females, lower income helps to predict ASPD development and even some other personality disorders like borderline personality disorder (Byrd et al. 2019). Similar results were echoed by McGrath and colleagues (2012) when it came to cases of abuse for men or women. Abused women with high functioning MAO-A genes were much greater predictors of antisocial behavior than their levels of MAO-A functioning. Mothers with high MAO-A genes may be less sensitive to stress (Kolla et al. 2014).

Fergusson and colleagues conducted a meta-analysis that looked at a twin study and the impact of one's upbringing and their biological history had on their psychopathology. Researchers found that one's personal biology and their non-shared upbringing were both of great significance in the development of ASPD. A shared environment had limited influence on the development of ASPD. Genetic influence related to serotonergic and dopaminergic development have been especially important to researchers in understanding ASPD, particularly involving MAO-A activity. It also has been found to impact the development of other disorders (Fergusson et al. 2011).

Conclusion

In an environment with abuse, neglect, and violence, the evolutionary advantages of ASPD may be much greater than that of altruism. Children who grow up in a home surrounded by violence may be more likely to survive by embracing violence than by being passive towards violence. Unfortunately, as the child grows older, ASPD becomes a maladaptive technique of functioning outside of a criminal enterprise (Del Giudice and Ellis 2016). For these reasons, it may be expected

that MAO-A levels that impact antisocial behavior may be managed by the environment.

Monogamy

Kyle Summers

East Carolina University, Greenville, NC, USA

Synonyms

Exclusive pair mating; Pair bonding

Definition

A mating system in which a single male and female form a pair-bond to produce offspring together for a significant period of time (at least one breeding season).

General Considerations

The term “monogamy” has been used to describe a variety of mating systems (Reichard 2003), but typically refers to specific affiliation with one mate, biparental care, and extra-pair aggression (territoriality and mate-guarding). Monogamy is rare in insects, fish, amphibians, and reptiles, but most avian species form monogamous pair-bonds. It is important to distinguish social monogamy, involving social affiliation in the context of pair-bonding, from genetic monogamy, with parentage confined to the socially bonded pair (Reichard 2003). Genetic monogamy is rare compared even to social monogamy (Reichard 2003). The advent of accurate genetic testing methods revealed that many species assumed to be genetically monogamous due to close pair-bonding, were not genetically monogamous (e.g., Quinn et al. 1987).

Traditional explanations for the evolution of monogamy have focused on the importance of biparental care to the growth and survival of offspring (Lack 1968, Wittenberger and Tilson 1980). Logically, if the benefit of biparental care to offspring is high enough (relative to uniparental care) to exceed the reproductive output expected by either sex by desertion, then neither sex should desert.

Later hypotheses focused on a variety of other factors. For example, in their classic paper on mating systems, Emlen and Oring (1977) argued that environmental constraints might limit the ability of one sex (particularly males) to monopolize multiple mates. They focused on the spatial and temporal distribution of females. For example, if females are highly dispersed, then males may be unable to monopolize more than a single female due to constraints on the size of territory that can be defended. Komers and Brotherton (1997) developed a related hypothesis: that when females are solitary and defend a small home range, males may choose to defend only a single female as a risk reduction strategy. Some large scale comparative analyses have lent support to this hypothesis as a general explanation for mammalian monogamy (Lukas and Clutton-Brock 2013).

Another influential hypothesis is that the benefits of protection from infanticide to both females and males may have favored the evolution of monogamy (Van Schaik and Dunbar 1990). This hypothesis has also received some support from comparative analyses, although this remains controversial.

Davies (1989) argued convincingly for the key role of female-female aggression (in addition to male-male aggression) in the context of sexual conflict over parental investment as a key factor affecting the evolution of monogamy. Gowaty (1996) also focused on sexual conflict, highlighting constraints on females as a key factor influencing monogamy. In her “constrained female hypothesis,” which focused on sexual conflict, she argued that all females would benefit from mating with males of the highest genetic quality (and by cuckolding their mates in most cases), but that males of low genetic quality attempt to constrain females from extra-pair matings through helpful coercion (e.g., provisioning), aggressive coercion (e.g., mate guarding), and “resource brokering” (e.g., control of access to critical resources). More recently, there has been increased attention to the potential role of sexual conflict in driving monogamy in a variety of systems.

This is not a comprehensive list of the hypotheses proposed to explain the evolution of monogamy, and as Reichard (2003) argued, it is likely that there have been multiple distinct evolutionary pathways to monogamy in different lineages.

Genetic, Hormonal, and Neural Mechanisms

Prairie voles have been a model mammalian system for the study of monogamy. This species is adapted to life in the harsh environments of the grasslands of the central United States. Early studies on this species revealed male and female pairs sharing nests and having overlapping home ranges (reviewed in Ophir et al. 2012). A key component of monogamy is the phenomenon of pair-bonding, in which a long-lasting preferential

association is developed between two partners, typically involving selective contact, social affiliation, mate-guarding, and copulation. In the lab, prairie voles develop strong pair-bonds with intensive biparental care and partner preferences, consistent with monogamous pair-bonding (reviewed in Ophir et al. 2012).

A series of studies have begun to reveal the hormonal, neural, and genetic mechanisms underlying monogamy in this species. Vasopressin and the vasopressin receptor locus appear to play crucial roles in regulating male pair-bonding, contribution to parental care, and monogamy (Young and Wang 2004). For example, some paternal care behaviors are associated with variation in a microsatellite region upstream of the vasopressin receptor gene, with long alleles showing increased expression. Manipulation of the expression of the vasopressin receptor in the brain of male voles (and mice) increased partner preference for partners in pair-bonds (reviewed in Young and Wang 2004).

In females, oxytocin plays an important role in female pair-bonding and monogamy. The monogamous prairie vole (and pine voles) show higher densities of the vasopressin receptor (in males) and the oxytocin receptor (especially in females) in specific brain regions, compared to promiscuous species like the montane vole (Young and Wang 2004). Recent research has demonstrated that the concentration of oxytocin receptors in specific regions of the brain is associated with monogamous behavior (Ophir et al. 2012). Research suggests that a “pair-bonding neural circuit” may coordinate the effects of vasopressin and oxytocin via a dopaminergic-mediated reward system associated with the mesolimbic network (Young and Wang 2004).

Okhovat et al. (2015) investigated the genetic, hormonal, and neural correlates of variation in degree of monogamy in the field. They found that variation in extra-pair mating was associated with lower levels of vasopressin receptor expression in regions of the brain associated with spatial cognition and memory (e.g., the retrosplenial cortex). Genetic analysis of the receptor genes revealed variation associated with enhancer regions likely to influence levels of gene

expression, suggesting that unfaithful males have poor spatial memory and may consequently range more widely. This trait appears to have both costs and benefits, as males with the “wandering” variant are more likely to engage in extra-pair copulations, yet are in turn more likely to be cuckolded. Molecular evolutionary analyses provide evidence for the footprint of balancing selection at the vasopressin receptor locus variants, which is consistent with the possibility of a tradeoff in which fitness varies with the environment. Okhovat et al. (2015) suggest that lower receptor expression may be favored when densities are high, allowing males to take advantage of readily available opportunities for extra-pair copulations. In contrast, low densities may favor a more monogamous strategy of stable pair-bonding and mate guarding.

The neural circuits and hormonal mechanisms that influence pair-bonding and monogamy in prairie voles may be similar to mechanisms affecting affiliation and love in human mating systems (Ophir et al. 2012). For example, oxytocin has been demonstrated to affect levels of trust in human interactions (Zak et al. 2005), as well as other important components of social cohesion.

Ecological Factors Driving the Evolution of Monogamy

While it has been difficult to identify the ecological factors associated with the evolution of monogamy, progress has been made on this issue in some taxonomic groups. For example, research on a species of South American poison frog has revealed that a specific ecological factor is likely to have driven the evolution of both biparental care and monogamy.

In the South American poison frogs *Ranitomeya imitator* and *R. vanzolinii*, clutches are placed in arboreal oviposition sites (Brown et al. 2010). Males attend clutches and carry tadpoles singly, placing them in small phytotelmata (leaf axil pools). During development, tadpoles are fed with trophic (unfertilized) eggs, and males lead females to each phytotelmata while calling and physically courting them. Genetic

analyses on *R. imitator* revealed the first example of genetic monogamy in an amphibian (Brown et al. 2010; Tumulty et al. 2014). Observations revealed that *R. imitator* uses much smaller pools than a closely related species with male-only parental care with a promiscuous mating system (*R. variabilis*). Translocation and removal experiments in the field demonstrated that both the female and the male make crucial contributions to tadpole growth and survival in *R. imitator* (Brown et al. 2010; Tumulty et al. 2014), revealing the key interaction between pool size and the importance of biparental care.

A complementary comparative analysis across all frogs provided further evidence for the effect of pool size in driving increased levels of parental care in anurans, and for a strong association between the evolution of egg-feeding and biparental care in small pools (Brown et al. 2010). This result is consistent with the argument that the change to using small phytotelmata for breeding drove the evolution of biparental care and monogamy in *R. imitator* (Brown et al., 2010). The increased biparental investment required to raise tadpoles in small nutrient-deficient pools apparently makes mate desertion an unprofitable strategy for *R. imitator* (Tumulty et al. 2014).

Comparative Analyses in Vertebrates

The factors driving the evolution of monogamy in other taxa continue to be the subject of considerable debate. The value of biparental care to offspring has repeatedly been proposed as a key factor favoring monogamy in birds (e.g., Lack 1968), although this is not universally accepted. There is comparative evidence for an association between enhanced levels of parental care and paternity certainty in birds, although cause and effect is not clear. In fish, there are a variety of hypotheses concerning the evolution of monogamy (reviewed in Whiteman and Cote 2004), but no general agreement that any one explanation is valid for all (or most) taxa. In an analysis of 2545 mammalian taxa, Lukas and Clutton-Brock (2013) found that monogamy evolved from solitary female ancestry in which females occurred at

low density and had non-overlapping home ranges. Under these circumstances, males may achieve higher reproductive success by guarding a single female, rather than attempting to patrol the ranges of several females (Emlen and Oring 1977; Komers and Brotherton 1997; Brotherton and Komers 2003).

Monogamy tends to be rare in mammalian species, but is more common in primates than in other mammalian clades. Comparative analysis supports the hypothesis that the risk of infanticide was a key factor driving the evolution of monogamy across primates (Opie et al. 2013), although this conclusion has been disputed. In a comparative analysis across 230 species of primates using a Bayesian likelihood framework, Opie et al. (2013) found significant associations between social monogamy and female ranging pattern, male infanticide and male parental care. However, only male infanticide typically precedes the evolution of social monogamy. Opie et al. (2013) propose that infanticide may have been a key factor leading to pair-bonding early in the human lineage, followed by increased paternal care.

Pair-Bonding and Monogamy in Humans

The evolution of monogamy in human societies is a contentious topic, partly because of uncertainty regarding the reconstruction of ancestral behaviors from paleontological and comparative data, and partly because biologists and anthropologists do not always use the same definition when using the term monogamy. Ethnographic, historical, archaeological, and paleontological data indicate that human mating systems have been highly variable over the course of human history, although monogamy does appear to have been an unusually common social arrangement during much of human history. Phylogenetic reconstructions of pair-bonding and marriage practices across human hunter-gatherer societies suggest that monogamous pairings are an ancient practice (Walker et al. 2011), as do some paleontological reconstructions of ancestral traits. While it is likely that some level of polygamy characterized ancient humans (as it does traditional cultures and

some modern societies), ancestral state reconstruction and other evidence supports the argument that the mating system was characterized by monogamy and low reproductive skew (Walker et al. 2011). Also, arranged marriages in the context of exchange between kin groups (Chapais 2013) are probably an ancient (ancestral) practice in the humans. However, this system of reciprocal exchange (managed by relatives) is unlikely to have evolved until after biparental care and long-term investment in offspring became established.

Any attempt to explain human monogamy must address a large number of unique peculiarities that characterize this lineage. These include: long juvenile period, concealed ovulation, menopause, extensive paternal care, language use and advanced intelligence, coordinated intergroup aggression, among many other traits (Alexander and Noonan 1979).

Richard D. Alexander, in a series of seminal papers, developed a detailed argument concerning the role of monogamous pair-bonding in the evolution of the human social systems, relating monogamy to many of the traits that uniquely characterize the human lineage (e.g., Alexander and Tinkle 1968, Alexander 1979, Alexander and Noonan 1979). Alexander argued that the human lineage was unique in the degree to which members engaged in within-group cooperation to facilitate effective between group competition (Alexander and Tinkle 1968, Alexander and Noonan 1979). This kind of competition is characteristic of chimpanzees as well as human hunter gatherers but is more complex, hierarchical, and extreme in the human lineage.

Alexander argued that females were able to develop and maintain consort relationships with individual males within multimale/multifemale groups, in part through the evolution of concealed ovulation (requiring long-term association and repeated copulation on the part of the male to ensure paternity). These consort relationships benefitted the participating males through paternity assurance and by providing the opportunity for providing effective investment in the male's own offspring. They argued that this would provide benefits to the female in the form of

investment by the associated male, including (possibly) protection from aggression or infanticide by other males. Strassmann (1981) argued cogently that this hypothesis was likely to apply specifically to low status males, as high status males would have much higher incentive to engage in a polygynous mating strategy at the expense of investment in any single female or her offspring. A key issue in explaining the evolution of monogamous pair-bonds is why males would invest in protecting a single female and caring for her offspring as opposed to investing in acquiring further matings (Gavrilets 2012), an issue that Strassmann (1981) addressed directly.

The obvious problem with this hypothesis is that dominant males should break up these exclusive associations between females and subordinate males and mate with the females themselves to enhance their own reproductive success. However, following Alexander and Tinkle (1968), Alexander and Noonan (1979) argued that as intergroup competition increased in importance among rival groups in the human lineage, this enhanced the value of subordinate males to dominants with groups, imposing constraints on the optimal levels of despotism and reproductive skew that could be imposed by dominant males at the expense of subordinates. Alexander (1979) coined the term "Socially Imposed Monogamy" (SIM) to describe this trend. This type of monogamy stood in contrast to what Alexander (1979) referred to as "ecologically imposed monogamy," in which environmental conditions are so harsh that males are unable to co-exist with more than a single female and her offspring in a single territory.

I note here that the idea that pair-bonding may frequently have developed in the context of protection of offspring from infanticide (as supported by comparative analyses across primates: Opie et al. 2013) is not inconsistent with the hypothesis developed by Alexander and Noonan (1979) and Strassmann (1981) for early humans. Certainly, females in multifemale/multimale groups would benefit from protection from dominants who might kill their offspring if there was a significant probability they were sired by another male, and subordinate males might benefit from protecting

the offspring of a female that they were able to mate with. Dominant males might be reluctant to force the issue if subordinates were valuable in intergroup aggression, as posited by Alexander and Noonan (1979).

Using a game theoretic model, Gavrilets (2012) argued that previous hypotheses focused on communal care, mate guarding, and mate provisioning did not have viable mechanisms promoting the evolution of pair-bonding, but that a model incorporating male heterogeneity, assortative mating, and female choice for subordinate paternal males did. This model bears striking resemblance to the hypothesis developed by Strassmann (1981) but does not explain why pair-bonding is tolerated by dominants. Gavrilets (2012) posits that the combination of provisioning as a profitable strategy for subordinate males, and male preference for such provisioning, is sufficient to drive the evolution of pair-bonding. Yet dominant males in primate societies are quite capable of (and intent on) breaking up consortships and claiming paternity for themselves. In this context, Alexander's (1979) hypothesis provides a key missing element: the effect of intergroup competition as a potent incentive to dominants to concede reproduction to subordinates.

Recently, Chapais (2013) developed a comprehensive theory of the sequential evolution of human societies with a focus on monogamy and kinship alliances within and among groups, using a phylogenetic approach and logical arguments concerning likely trajectories based on evolutionary ecological considerations. Alexander (1979) proposed that the ancestral mating system of the common ancestor of humans and chimpanzees was probably multimale/multifemale groups, as found in chimpanzees. Chapais (2013) was skeptical of this idea, arguing instead for multimale polygynous units on the basis of parsimony in comparison with other primate social systems. However, this argument ignores the possibility of a gradual transition from multimale/multifemale promiscuity through the gradual concession of reproductive access to subordinates in the context of increasing intergroup competition.

With specific reference to the transition to monogamy in early human groups, Chapais (2013) proposed four possible explanations (starting from an ancestral state involving groups of multiple one male/multifemale units). Two hypotheses (increasing costs of paternal care and increasing difficulty of herding more than a single female) apply specifically to groups comprised of one male/multifemale units. The other two do not assume this structure. One idea is that dominants face a trade-off when suppressing or displacing subordinates, because subordinates are of high value to dominants for their support in the context of intergroup competition. This is precisely the hypothesis developed by Alexander (discussed above).

The adoption of increasingly sophisticated weaponry may have had a leveling effect on within-group relationships, making it more difficult for dominants to suppress or displace subordinates (Bingham 1999). There is a variety of evidence supporting the leveling effects of (offensive) weaponry (reviewed in Summers 2005). However, this effect is likely to have followed rather than preceded the rise of intergroup competition, which was probably the key selection pressure favoring the development of sophisticated weaponry in the first place (Alexander 1979).

Chapais (2013) argued that once the transition to monogamy was complete, it set the stage for increasing cooperation between mating pairs. One important factor in this context may have been economic collaboration in the context of food acquisition, preparation, and consumption. Wrangham (2010) proposed that cooking rendered food a highly valuable resource, which could have favored the evolution of pair-bonding itself, as females might have required male protection to guard them against other males, in exchange for food. Chapais (2013) argued that monogamy probably predated the invention of cooking but was likely to have been a major force favoring economic cooperation between mated pairs. Chapais (2013) also argued that increasing costs of parental care may have favored increasing male contributions to biparental care. He did not specify the reasons for these increasing

costs, but this possibility fits in very well with Alexander's argument that the balancing act between intergroup competition and within-group cooperation would strongly favor increased intelligence and increasing parental investment in producing high-quality offspring (Alexander 1979, 1989). Chapais (2013) goes on to argue that the establishment of monogamy would have dramatically enhanced cooperation between multifamily groups, due to the development of patrilineal kinship ties through the exchange of females between groups in the context of male philopatry. This is likely to have had a major effect on human social evolution.

Whatever level of monogamy obtained in early humans, the advent of agriculture led to major changes, with many large, hierarchical societies characterized by extreme despotism and polygyny (Betzig 1986). This rise corresponded closely with a sedentary lifestyle, ecological constraints in the form of dependence on (limited) fertile soils, opportunities for accumulation and preservation of wealth, and cross-generational inheritance of resources that characterized the transition to agriculture. However, over the course of more recent human history levels of reproductive despotism began to decline, to the point that the majority of people currently live in societies that consider monogamous relationships to be the norm. Alexander (1979) argued that increasing levels of intergroup competition eventually overcame the factors favoring despotism unleashed by the advent of agriculture and forced despotic (and highly polygynous) rulers to concede more reproduction to subordinates in society, in order to obtain the allegiance of those subordinates in competition against other groups. He argued that intergroup competition increased in intensity in step with the rise of organized nation-states. Betzig (1986) argued instead that the increasing value of specialized skills and labor driven by the rise of industrialization made the value of skilled workers to rulers high enough that they were willing to reduce reproductive monopolization in order to retain such workers in the workforce. Both Alexander (1979) and Betzig (1986) emphasize "concessions" on the part of rulers as a key factor in the rise of monogamy, although they do

not rule out collective action on the part of subordinates.

MacDonald (1995), in a careful historical analysis of the rise of monogamy in Western Europe, agrees that the two factors emphasized by Alexander (1979) and Betzig (1986) were likely important, but argues that their explanations are incomplete and that at least three other factors played major roles. First, he argues that males of low or middle status may have acted collectively to effectively impose social monogamy (as a rule designed as an opportunity-leveling mechanism across males). Second, in some societies women may have been able to exert sufficient political power to push the society toward rules requiring social monogamy (note that polygyny often imposes a high cost on females). Finally, the Christian Church, as a hierarchical nexus of political power that was often in competition for power and resources with the traditional political elites (i.e., traditional royalty), frequently had reason and opportunity to impose rules that restricted the royal power and dominance, in some cases by restricting polygyny and hence the size of royal families. MacDonald (1995) provides an in-depth defense of the importance of these three factors, using a careful analysis of the historical record. He concludes that, while each of the five factors affecting the rise of monogamy is logical from an evolutionary perspective, their interaction is complex and historically contingent, making it difficult to predict exactly which societies would develop monogamy.

An additional factor potentially favoring monogamy is lineage competition. The importance of cross-generational inheritance of wealth on the ability to successfully establish and maintain a family increased with the advent of increasing societal size and complexity (reaching extremes following the demographic transition), and long-term lineage persistence came to depend on high investment in the joint offspring of monogamous pairs, potentially providing a further impetus toward monogamy (reviewed in Low 2000).

A variety of other theories for the evolution of monogamy have been discussed in the recent literature, although none have gained widespread

acceptance. For example, Bauch and McElreath (2016) developed a model of the interaction between sexually transmitted disease and socially imposed monogamy in the context of group size. The evolution of monogamy in humans has been and remains a contentious issue, and vigorous debate about the topic is likely to continue in the scientific (and popular) literature for the foreseeable future.

Definition

Moral concerns describe bioethical issues that have been raised concerning the application of human

biotechnologies, such as abortion, in vitro fertilization, embryo selection, preimplantation genetic diagnosis, and germ line gene therapy, that collectively enhance reproductive choice.

Introduction

The *reproductive choice revolution* has emerged as a voluntary, market-based phenomenon. It presents different moral issues to those associated with the “first-wave” eugenics movement initiated by the Victorian-era polymath Sir Francis Galton. Moral concerns are changing as biotechnology, especially in vitro fertilization (IVF) with preimplantation screening, reduces reliance on abortion as a method of curbing genetic disease, this historically having been an obstacle to Christian approval. Christian opposition to abortion was also an important source of criticism leveled against certain proponents of first-wave eugenics, such as Margaret Sanger. Presently, the Catholic Church continues to condemn the discarding of single-cell embryos as sinful, based on the premise that the right to life begins with the setting of the genotype at conception.

One set of moral concerns raised in response to new *reproductive technologies* (which include IVF and preimplantation genetic screening, among others) involves the existing and rapidly growing market demand for techniques that maximize informed reproductive choice. Other concerns are prospective – the risks posed to children and society by the premature and uneven uptake of reproductive technology. Both sets of issues raise questions, which for many contemporary bioethicists are made sensitive by the historical experience of certain countries that adopted legislation congruent with the first-wave eugenics movement, such as sterilization laws – the issue therefore being: Can government involvement in human reproductive affairs ever be justified?

Review

The Reproductive Technology Market

As early as the 1980s, evidence that consumer demand was driving reproductive technological

innovation was reported by historian Daniel Kevles (1995/1985). The trend had been evident in the genetic counseling movement, in which hospitals offered voluntary advice to parents desiring children. The practice remains widespread, perhaps motivated by the same “eugenic impulse” that influenced the development of medical genetics (Comfort 2012). This motivation is to be expected if evolved strategies for passing on “good genes” are part of humans’ evolved psychology. By the end of the century, the IVF market was booming: a multibillion dollar worldwide industry that offers clients add-ons that are, in the parlance of Galton, “negative eugenics” (i.e., which curb the proliferation of undesirable traits) in the form of preimplantation screening of embryos as a means of avoiding genetic disease. The demand for “positive eugenics” (i.e., which promotes the proliferation of desirable physical or psychological traits) is likely to follow on from the already established negative eugenics, barring multilateral agreements that prevent “procreative tourism” aimed at circumventing restrictive laws (Monni et al. 2006).

Premature and Uneven Uptake of Reproductive Technology

As the sciences of genetics and biosocial sociology are still developing, there is a risk of making maladaptive choices based on bad science. This risk is downplayed by some bioethicists, such as Ingmar Persson and Julian Savulescu (2014) and George Church (2014), who support parents’ right to determine their children’s genome using the full repertoire of reproductive technologies, including the emerging capacity to edit the genome. This view has been criticized based partly on the danger of technological immaturity.

One risky application is recommended by Savulescu and Peter Singer, who propose using gene editing to eliminate ethnocentrism. They envisage producing individuals who do not favor their own children or ethnic groups. Arguably, such an outcome would dissolve the family as a locus of strong interpersonal bonds and prove maladaptive by reducing motivation to invest in genetically similar individuals, whether kin or co-ethnics.

The risk of premature uptake is increased by uncertainty about what is meant by “desirable.” It

is clear from the writings of first-wave eugenicists that “desirable” was synonymous with social good, the aim being to promote civilization-enhancing traits, such as communal orientation and altruism. Modern conceptions of “desirability” may revolve around self-interest to a greater degree. It has been argued that modern populations are relatively more individually selected than historical ones (which tended toward group selection; Woodley of Menie et al. 2017). In as much as the regime of individual-level selection that started in the Late Modern Era has led to *dysgenic consequences* (such as declining general intelligence; Woodley of Menie et al. 2017), conscious control of genetics could facilitate maladaptive outcomes, especially if the sorts of traits deemed “desirable” under the present selection regime enhance individual-level competitiveness in a non-pro-social fashion, such as via the inadvertent promotion of psychopathic traits, a concern first raised by Cattell (1987). Indeed, potentially consistent with this concern are the findings of Latham and von Stumm (2017), who, in a survey of 142 mothers found that they considered extraversion (whose facets include sensation-seeking and dominance) to be more desirable than the potentially more group selected personality dimension of conscientiousness (whose facets include dutifulness and self-discipline) and intelligence in their offspring.

Good science can also engender moral concerns. The uneven uptake of reproductive technological services, including those proven safe for individuals, could reflect and exacerbate existing inequalities. A gynecologist providing preimplantation screening with IVF has noted that the wealthy can find ways to access reproductive technology, but the poor must rely on abortions (Monni et al. 2006). Noah Harari (2015) argues that wealthy individuals will get a head start in using reproductive technologies and other enhancements, giving their children genetic as well as financial advantages. Other early beneficiaries will include slow life history strategists, if their ‘genetic quality’ impulse includes treating preimplantation screening as a form of parental investment. Uneven uptake could lead to structural biological inequalities (de facto castes) between the offspring of those who can afford

access to such technologies and those who cannot. Assortative mating alone can potentially produce dramatic divergence in average IQ (Harpending and Cochran 2015). Harari envisages these castes as a step toward speciation. Even without such fundamental change, castes would risk fracturing democratic communities by impeding social mobility (reviewed in Salter 2015a).

Can Government Involvement in ‘Eugenics’ Be Justified?

First-wave eugenics failed ethically in the eyes of our contemporary, relatively more individually selected population, when it involved curtailment of civil liberties, most notoriously through involuntary sterilization. In that light, socialized eugenics is a known moral risk. Yet government regulation of the eugenics market seems necessary to discourage dangerous choices and to universalize benefits, especially when considered in terms of the regime of individual-level selection that predominates in the contemporary West. Regulation is a relatively passive stance compared to the active government promotion of eugenics responsible for transgressing individual-level liberties in the past. It has been argued that the emerging reproductive technology market that characterizes the modern “second-wave eugenics” may be safest when active citizens are regulated by relatively passive governments (see Salter 2015b).

The scope for ethical government initiative in driving reproductive choice may be small. Government-directed reproductive outcomes may be most acceptable as a secondary effect of policies incidental to this objective or when the latter are sufficient to justify the policy.

Conclusion

The imposition of reproductive choices typical in first-wave eugenics has been replaced by a rapidly growing consumer-led market. The new reproductive technologies, most notably IVF with pre-implantation genetic screening, have shifted moral concerns from civil rights to issues of equality of market access and the potential dangers, to individuals and society, of premature and

uneven uptake. It appears likely for ethical reasons that governments will regulate the reproductive choice market, however their role is likely to be less direct than in the past.

Definition

“Moral” emotions are those thought to relate to the capacity for human morality. Examples of

such emotion types include disgust, shame, pride, anger, guilt, compassion, and gratitude.

Introduction

Emotion can be defined with reference to its input conditions, its characteristic output, and the internal mechanisms that mediate input and output. It is generally accepted that at least some emotion kinds are adaptive products of evolution. An appraisal that the environment affords an opportunity or threat is the input condition for such emotion kinds, and the output is some behavior that (if successful) constitutes an adaptive response to the situation. The internal mechanism prompting the adaptive action is a coordinated set of changes in appraisal, expression (facial, vocal), action tendencies (fleeing, threat displays), feeling, and physiological arousal that together explain how the adaptive response takes place and the characteristic internal sensations associated with the emotion.

Moral emotions are those emotion types linked with our capacity for moral thinking or moral action. They are thought to either (i) enable a capacity for moral action or (ii) contribute to the project of grounding or justifying moral norms (i.e., normative statements that define moral obligations). Section “[Grounding Moral Norms](#)” discusses the relationship between moral emotions and the project of grounding moral norms. Section “[Evolved Emotions](#)” introduces the idea that (at least some emotion types) evolved for their adaptive significance. Section “[Moral Emotion Types](#)” discusses some putative moral emotion types that have been studied in recent years.

Grounding Moral Norms

Finding some sort of nonarbitrary ground for moral norms is the traditional “holy grail” of moral philosophy. Virtue ethics, divine command theory, rationalism, and sentimentalism are four broad traditions of thought that engage in this project. Divine command theory takes moral

norms to be grounded by a heteronomous force, namely, the Christian conception of God. Virtue ethics, a tradition initiated by Aristotle in the *Nicomachean Ethics*, grounds the virtuous (good) action of a thing in its ability to perform its “natural” or “proper” function (in the human case, this capacity is the exercise of rationality; see Korsgaard 2008). The rationalist tradition, exemplified by Kant’s *Groundwork for the Metaphysics of Morals* (1785/2003), sees moral norms grounded in autonomous reason – individuals rationally reflecting on the norms appropriate to the situation at hand.

None of the accounts just described support the idea that emotion can, on its own, ground moral norms. It is within sentimental moral theories, however, that emotions perhaps play the most central role in a more modest project, namely, explaining our *capacity* for moral behavior. Sentimentalism is perhaps best understood in contrast with rationalism. Rationalism claims that it is our capacity to reason, not our capacity to feel (i.e., to experience emotion), that undergirds the human capacity for moral behavior. The rationalist approach has a long and venerable philosophical heritage. Plato’s *Timaeus* (360 BCE) presents a myth in which gods invent human heads whose distinctive faculty is reason. Recognizing the heads requires bodies – full of unbridled desires and passions – to help them move through the world. The struggle to live a moral human life is expressed as the struggle of the head to control the body through the sublimation of the body’s passions toward virtuous ends.

In the seventeenth and eighteenth centuries, the sentimentalists Hobbes and Hume instrumentalized practical reason. Hume, for instance, demoted reason, describing it as a “slave of the passions” that can “never pretend to any other office than to serve and obey them” (Hume 1738, p. 462). Hume’s point was that the passions determined which ends were desirable, while reason acted as a conscientious servant, formulating plans to deliver those ends. Moral knowledge was attained by an “immediate feeling and finer internal sense,” rather than a “chain of argument and induction” (Hume 1777, p. 2). For the

sentimentalists, reason alone can enable the inference that a particular action will lead to an avoidable loss of human life, but it cannot tell us whether this loss ought to be avoided.

The focus of Hume (and Hobbes before him) was on casting emotion as (i) a causal antecedent to moral judgment and (ii) a sufficient ground for the legitimacy of moral claims. But this is not to say that sentimentalism offers succor to the moral realist who wants to ground morality in facts extraneous to our nature as embodied beings. We now set aside this latter project and return to the more modest project of explaining our capacity for moral behavior and decision-making and how we foster conditions conducive to its exercise.

Since the Enlightenment, rationalism has exerted an influential hold within moral philosophy. The rationalist tradition takes cool-headed reason to represent the ideal conditions for moral decision-making. Kant (1785) is the canonical representative of this view and has exerted a tremendous impact on modern moral and political philosophers (e.g., Rawls 1971), many of whom have attempted to follow Kant by providing a foundation for ethics derived from the meaning of rationality itself. However, rationalism has also dominated much of twentieth-century psychology. Kohlberg’s work was a sustained attack on “irrational emotive theories” (1971, p. 188), and his cognitive-developmental theory was an important part of the cognitive revolution. More recently, neo-sentimentalists have claimed that moral judgments are produced by automatic intuitive or emotional processes. Cushman et al. (2010) describe two related ideas associated with neo-sentimentalism in contemporary literature on moral psychology. The first “claims that moral judgment takes the form of intuition, accomplished by rapid, automatic and unconscious psychological processes,” while the second “claims that moral judgment is driven primarily by affective responses” (p. 47). Empirical evidence cited in favor of the first claim focuses on demonstrations of people’s inability to articulate a rational basis for many of their most strongly held moral beliefs. Evidence favoring the second challenge draws on neuroscientific data relating to localized brain regions (Ciaramelli et al. 2007) but also

includes behavioral studies of moral judgment that invoke affective manipulations.

Two influential neo-sentimentalist proposals have come from Damasio (2006) and Haidt (2001) in recent years. Both figures emphasize the importance of emotional and/or intuitive processes in moral decision-making. In particular, both claim that moral judgments are produced by automatic intuitive or emotional processes. They also claim that, when we think we are deliberating about the rightness of a given moral principle, we are not so much reasoning from first principles as we are engaging in post hoc rationalization. That is, we are simply reasoning in whatever way will support the emotionally driven judgment we have already pledged allegiance to. Haidt's social intuitionist model aims to explain how this post hoc rationalization occurs. Haidt claims that "moral dumbfounding" occurs when a judgment, solution, or other conclusion appears suddenly and effortlessly in consciousness, without any awareness by the person of the mental processes that led to the outcome.

Proponents of neo-sentimentalism need not be read as claiming that emotional and/or intuitive processes actually ground or justify specific moral claims. Rather they can be seen as showing that the capacity to feel certain emotions (i.e., moral emotions) is tied up with our *capacity* to formulate moral norms (see Kitcher 1994 for discussion). Despite its popularity, neo-sentimentalism has met with skepticism, for instance, by champions of "universal moral grammar" (Hauser 2007). Hauser and others have claimed that moral judgment requires computations performed over representations of agents, intentions, and causal relationships in order to output judgments of right and wrong. Information processing of this sort must precede an emotional response, so the argument goes, and thus it must be that moral judgment leads to emotion, not the other way around. One promising way to make progress in this debate about the role emotions play in our capacity to be moral is to explain the adaptive function of particular emotion types in relation as facilitating conformity to moral norms. The remainder of the article focuses on this project. First, we motivate the claim that emotions evolved.

Evolved Emotions

Evolutionary approaches to emotion describe them in terms of the function they currently perform or performed in our ancestral past. The claim that at least some human emotions evolved and are shared with lower mammalian species is now uncontroversial and began with Darwin's *Expression of the Emotions in Man and Animals* (1872). Darwin himself defined emotions as subjective feelings. Following Herbert Spencer, Darwin distinguished emotions as feelings caused by external states, in contrast to feelings caused by bodily states, such as hunger and pain. Later evolutionary theorists have preferred behavioral and physiological definitions of emotion, and so consequently Darwin's theory of emotional expression has been seen as a theory of the emotions themselves. The central principle Darwin proposed to explain the evolution of expression was the "principle of serviceable associated habits." Darwin believed that instinctive behaviors derive from habits. The consistent acquisition of the same habit for many generations causes it to become hereditary, or instinctive, as a result of the inheritance of acquired characteristics.

The founders of ethology saw themselves as the direct heirs of Darwin's work on mental evolution (Lorenz 1965). They retained Darwin's principles but reinterpreted them to fit the theory of evolution as it emerged in the 1930s in the "modern synthesis" of Darwinism and Mendelian genetics. The principle of serviceable associated habits was transformed into the ethological concepts of "ritualization" and "derived activity" (Tinbergen 1952). Derived activities are behaviors that originally evolved for one purpose but were later selected for another purpose. Ritualized behaviors are derived activities that originally evolved to fulfill some practical function but were later selected to function as signals. For example, grimacing in anger may have originally evolved to enable our ancestors to prepare to attack an opponent using their sharp canine teeth. We have evolved such that we no longer have fang-like canines, and yet we still grimace in anger. The derived activities account sees grimacing serving a derivative, signalling

function of indicating that one is angry and that the possibility of attack is imminent. Grimacing was originally selected to enable direct attack, and through this association came to serve a secondary function of signalling to conspecifics the possibility of attack. The concept of ritualization allowed ethology to reconstruct Darwin's principle of serviceable associated habits while avoiding his commitment to the inheritance of acquired characteristics. Darwin's descriptions of the psychological rewards that led to the reinforcement of emotional behaviors are equally plausible as descriptions of the original selective advantage of those behaviors.

Darwin's detailed accounts of human facial expressions were confirmed and extended during the 1960s and early 1970s, and many of his suggested homologies between human and primate facial expressions were confirmed. It became generally accepted that some emotional expressions, the so-called basic emotions, are found in all cultures and have an evolutionary history at least as long as the history of the human species (Ekman 1973). The basic emotions are usually referred to as fear, anger, disgust, contempt, joy, sadness, and surprise, although in normal usage each of these words has a much wider meaning. Each basic emotion corresponds to an "affect program" stored somewhere in the brain. When activated, this program coordinates a complex of actions that include facial expression, autonomic nervous system changes, expressive vocal changes, and muscular-skeletal responses such as flinching or orienting. The concept of an affect program inherits many of the features of the ethological concept of a "fixed action pattern." Both concepts suggest that certain apparently complex behaviors are, in reality, atomic units of behavior that unfold in the same stereotyped sequence whenever they are triggered. The affect programs are controlled by an "automatic appraisal mechanism." This is a specialized neural system that applies its own distinctive rules for stimulus evaluation to a limited set of data derived from the earliest stages of the processing of perceptual information. Considered together, the appraisal mechanisms and affect programs form a cognitive "module" in the sense favored

by more recent evolutionary psychologists (Barkow et al. 1992).

Evolutionary accounts of basic emotions have inspired work on whether "nonbasic" emotions (such as gratitude) may have also evolved (► [Emotion](#)). This work is discussed in the section below with a focus on emotion types for which an adaptive function related to conformity with moral norms is available.

Moral Emotion Types

Considering the unique adaptive functions of different moral emotion types is the basis of a more complex account of how the "suite" of moral emotions has, as a whole, evolved to support the capacity for moral behavior. Below, we consider a number of putative moral emotion types (disgust, shame, pride, indignation, guilt, compassion, and gratitude). We focus on adaptationist hypotheses that relate to obeying rules or socially sanctioned behaviors, or acting so as to benefit others.

Disgust. Kelly's (2011) influential synthesis of work on disgust suggests that the emotion combines a taste-aversion mechanism with a mechanism for avoiding infection and parasitism. Kelly argues that disgust is uniquely human. It is an example of the co-option and developmental entanglement that occurs as an evolving lineage confronts new adaptive challenges and must solve them by modifying existing features. Both elements of the disgust response have homologues or analogs in other species. It is their entanglement that creates a uniquely human emotion. On this account, moral disgust represents a further piece of evolutionary tinkering in which the emotion of disgust was co-opted to help enforce conformity with in-group norms. More recent work accords with this view, with moral disgust described as disgust that evolved to "respond to sociomoral elicitors [...] such as immoral acts" (Russell and Giner-Sorolla 2013, p. 330).

Pride and shame. Although competing explanations of the evolution of pride and shame are extant in the literature, a consensus is emerging. Behaviors homologous to those we associate with pride and shame are components of displays

employed by nonhuman primates (and other mammals) during the negotiation or affirmation of relative rank. We can label the emotions that underlie such displays as “protopride” and “protoshame.” In a competitive environment, the expression of protoshame signals the actor’s acceptance of a subordinate position in a hierarchy. It functions to deflect aggression from the dominant party. The expression of protopride, in contrast, signals the actor’s dominance. Importantly, protopride is a pleasant feeling, while protoshame is unpleasant. Fessler (1999) argues that protopride and protoshame were selected for in primates because they promoted dominance-seeking behaviors, which increased the chances of reproductive success. These emotions are the phylogenetic ancestors of pride and shame in human beings (Fessler 1999, 2004).

However, Clark (2012) has argued that humans retain the ability to experience protopride and protoshame alongside their more sophisticated descendants, pride and shame. Pride and shame are more cognitively complex than protopride and protoshame. They require that the organism has “theory of mind” – the capacity to attribute mental states to other individuals. They also serve a different adaptive function in the relatively cooperative, nonhostile environments human beings inhabit. In such contexts, pride and shame are experienced in response to the actual or imagined assessment of an actor’s behavior by an audience. If the assessment inspires the contempt or pity of the audience, the actor feels shame. If the assessment inspires the envy or admiration of the audience, the actor feels pride. In the cooperative context, then, pride and shame encourage the actor to seek the admiration and envy of others, which in turn encourages them to act in ways that support the well-being of the group (Fessler 1999). In this way, these emotions inspire adherence to socially sanctioned norm-governed behavior.

Anger. Philosophers sometimes draw a distinction between simple or “basic” anger and more cognitively complex varieties such as resentment or moral indignation. Say that a simple form of anger arises in response to feeling a sharp jolt in the back from an unknown cause while

standing in line at the supermarket. The reflex-like expression of basic anger, consistent with a basic appraisal (however implicit) of goal obstruction, is one we likely share with nonhuman species (Ekman 1973). In contrast, resentment or moral indignation is generally understood as accompanied by a more complex appraisal, namely, the judgment another party or parties are worthy of blame (Wallace 2008). In the supermarket example, resentment might only arise upon turning around and seeing that the cause of the jolt in the back was a person indelicately attempting to queue-jump. This case requires making an appraisal that has a more specific content, namely, that the goal obstruction arousing the initial anger has been caused by a third party and that it was wrong of that party to cause it.

An appraisal of this sort is consistent with Rozin et al.’s (1999) association of anger with violations of the standard of autonomy, which refers to concerns about fairness, reciprocity, and the prevention of harm. Anger elicited in this way could have served three distinct adaptive functions. The first is encouraging behavior that is reciprocal and fair (and therefore likely to lead to the survival of the population at large). The second is motivating an aggressive response to hostility, which would have increased the likelihood of the emoter’s survival. The third is that an angry expression would serve as an important social signal of imminent threat, encouraging the opponent to flee the situation.

Guilt. The case of guilt provides a useful example of the role evolutionary game-theoretic scenarios play in establishing adaptationist hypotheses for emotions and thereby connecting them to the moral domain. Modeling such scenarios is especially useful when considering the role of moral emotions in promoting the survival of the group at the cost of the individual. Unlike the case of anger, guilt-prone individuals act so as to benefit the group at a cost to themselves. That is to say that they behave altruistically, even in cases when they do not expect to be caught. Those who feel guilty after a transgression accept punishment readily and even punish themselves. For this reason, one might think that guilt evolved for its benefits to groups, rather than individuals.

Recent evolutionary game-theoretic modeling (Rosenstock and O'Connor 2018) shows that when actors play an iterated prisoner's dilemma and sometimes err, guilt can evolve to facilitate forgiveness and social reparation. Guilt functions in this setting by either ensuring the trustworthiness of apology or by leading apologizers to pay a cost. This model adds to previous literature on the evolution of apology by showing how both emotion reading and costly apology can interact to stabilize guilt, thereby describing the environmental conditions that would allow guilt to evolve.

Compassion and gratitude. Accounts of the evolution of compassion and gratitude build on the literature on biological altruism. In evolutionary biology, altruism refers to an action that benefits another at a cost to the actor (such as sharing food). The evolution of altruism is explained either by "kin selection" (► [Kin Selection](#)) or "group selection" (► [Group Selection](#)). Kin selection proposes that an altruistic gene will be favored by natural selection when it motivates action that confers a fitness advantage to a recipient of the same kin (Hamilton 1964). Group selection proposes an alternative mechanism by which altruism spreads as a trait in a population: altruistic actions (like helping conspecifics on a hunting trip) increase the fitness of the group even though it decreases fitness for individuals. Groups with larger numbers of altruists will be more likely to survive than those with lower numbers, and so altruism will spread as a trait through the mechanism of group selection.

The relation between altruistic behavior and pro-social emotions is a matter of some contest. However, one influential argument by Trivers (1971) claims that compassion (used synonymously with "sympathy") evolved within a complex system of other emotional states (including gratitude, guilt, liking, and anger) to enable nonkin to initiate, maintain, and regulate reciprocal, altruistic relationships (see also Nesse 1990). Within this system of emotions, compassion emerged as a state that motivates altruism in mutually beneficial relationships and contexts. It is an emotional reaction that involves feelings of concern and sorrow for the other party, based on an apprehension of that party's emotional state.

Gratitude is relatively understudied compared with other moral emotions. Like compassion, gratitude motivates altruistic behavior but stems from the appraisal that one has just received help or aid from another, which creates a motivational state to either "return the favor" (call this "direct reciprocity") or "pay it forward" (by helping someone else, also known as "upstream reciprocity"). Experiments show that gratitude in humans fosters pro-social behavior. In particular, the recipient of a favor is more likely to engage in acts of both direct and indirect reciprocity. Recent modeling scenarios by Nowak and Roch (2007) suggest both that "spontaneous" cooperators are outcompeted by gratitude-related upstream cooperators (i.e., that gratitude is a better motivator of cooperation) and, moreover, that upstream reciprocity greatly enhances the level of altruism in a population.

Conclusion

The surge of literature on the moral emotions over the past 30 years (e.g., Haidt 2003) represents a shift away from the (normative) question of what grounds or justifies moral norms and toward the (descriptive) question of what capacity or capacities in human beings enable moral behavior. While these two projects should be undertaken in tandem, the focus on the latter question holds the promise of explaining much of moral behavior by recourse to "instinct-like" emotional capacities that evolved to encourage norm conformity, especially in relation to norms often described using moral language.

While the hypothesis that basic emotions are adaptations is well-established, the hypothesis that "moral" emotions evolved for their role in enforcing norm conformity is more contested. This is so for multiple reasons. One is that the latter hypothesis requires mapping readily observable behaviors (such as cooperating by sharing food) to normative moral concepts (e.g., fairness, generosity, etc.). Another is that establishing that certain emotion-inspired behaviors increase fitness at the level of kin or group selection (e.g., in the case of compassion and gratitude) requires

game-theoretic modeling of change in frequencies of a trait (e.g., cooperation) in a population over time. Finally, establishing how a “suite” of moral emotions may have evolved over phylogenetic time as part of a multilevel selection strategy would require modeling scenarios of multiple behavioral traits that act as proxies for the suite of emotion types under investigation. The next step would require moral psychologists and moral theorists to determine how much of moral behavior can be explained by exclusive appeal to the behavioral traits under consideration. This is an ambitious and valuable task in and of itself but one quite distinct from the project of justifying or grounding moral norms.

Definition

Inborn tendencies to act morally and to experience a sense of morality.

Introduction

Over the years, the concept of instinct has drifted in and out of favor in the natural and social sciences and has been defined in many different ways. Here, instincts are defined as natural inborn tendencies inherited by all members of a species to feel, think, and act in particular ways in response to particular internal and external triggers. Evolutionary theorists such as Pinker (2008) have invoked the concept of moral instincts. Moral instincts can be defined in two qualitatively different, but related, ways – (a) as instincts that induce individuals to *behave* in ways that people consider moral and to refrain from behaving in ways that people consider immoral and (b) as instincts that induce individuals to *categorize* certain phenomena as moral and immoral and to make moral judgments. People experience the second kind of moral instinct as positive and negative feelings, intuitions, and ideas that engender a sense of approval and disapproval about certain forms of conduct, desires, motives, character traits, and people. Darwin (1874) referred to them as the moral senses. The challenges faced by evolutionary theorists are to identify the mental mechanisms that dispose individuals to behave in moral ways and to make moral judgments and to explain how these mechanisms evolved. These challenges entail explaining why people feel that they and others ought and ought not to behave in certain ways; why people view certain phenomena as right or wrong, good or bad, fair or unfair, and virtuous or vicious; and why people pass judgment on themselves and others for behaving in ways that uphold or violate moral standards.

Culturally Universal Moral Norms

Anthropologists and other social scientists have concluded that although people from different

cultures may develop different, culturally relative, moral norms, people from all known cultures view particular types of behavior as right and their opposites as wrong. For example, Boehm (2012) found that members of all the hunter-gatherer groups he surveyed considered generosity, group harmony, and cooperation good and excessive selfishness, bullying, murder, lying, cheating, stealing, incest, and adultery bad. In addition to these forms of conduct, other investigators have adduced evidence that people from all cultures view deference to legitimate authority and purity as moral, and their opposites as immoral. In summary, all cultures possess moral norms upholding (a) altruism, (b) support for one's group, (c) fairness, (d) respect for legitimate authority, and (e) purity.

Culturally Relative Moral Norms

Although people from all cultures consider these five forms of conduct moral, cultures differ in the salience of moral norms upholding these forms of conduct, the relative value they attach to each of them, and the particular kinds of social behavior that instantiate them. As Pinker (2008) has pointed out, Western cultures tend to consider moral norms opposing harming others and upholding care and justice as regnant; Japanese cultures tend to elevate norms pertaining to group solidarity; and Hindu and Orthodox Jewish cultures tend to place a high value on purity (e.g., as reflected in dietary restrictions) and authority (e.g., not insulting Mohammad). Other investigators have found that different groups within Western cultures also tend to place different values on different types of moral behavior. For example, liberals tend to value altruism and fairness more than conservatives do, whereas conservatives tend to value group loyalty, authority, and purity equally highly.

Different cultures and subcultures also may classify particular behaviors in different categories, producing cultural and individual differences in the instantiation of moral norms. For example, people may have different conceptions of what it means to help and to harm others and what it

means to treat others justly and unjustly; and they may harbor different ideas about what makes these forms of conduct right and wrong. Investigators have documented notable differences among cultures with respect to moral norms pertaining to sexual conduct, marital unions, preservation of life, and dietary restrictions. In addition, the threshold for the activation of moral instincts tends to be lower for in-group members than for out-group members (Greene 2013), and cultures may differ in the extent to which moral instincts are activated by nonhuman animals.

Theorists such as Haidt (2001) and Pinker (2008) have accounted for the evolution of culturally universal and culturally specific moral norms by suggesting that all people inherit mental mechanisms that endow them with a set of universal, species-specific moral intuitions, just as people from all cultures inherit mechanisms that endow them with the capacity to produce and to understand language. However, in the same way that people from different cultures acquire different languages, people from different cultures instantiate universal moral norms in different ways.

Origins of Instincts to Behave in Moral Ways

Evolutionary theory generates the expectation that instincts to behave morally originated either because they gave early humans an adaptive advantage or as by-products of other adaptations. Evolutionary theorists such as Alexander (1987), Krebs (2011), and Richerson and Boyd (2005) have suggested that the overriding adaptive function of moral instincts is to motivate members of groups to advance their interests in cooperative ways. Moral instincts induce members of groups to resist the temptation to advance their short-term personal interests in ways that diminish the long-term biological and genetic benefits they can reap from upholding the cooperative social orders of their groups. Cooperation can pay off by enabling members of groups to maximize the acquisition of resources, to engage in superior forms of defense,

and to outcompete selfish groups. “Inasmuch as every member benefits from a unified, cooperative group, one expects them to care about the society they live in, and to make an effort to improve and strengthen it similar to the way the spider repairs her web, and the beaver maintains the integrity of his dam. Each and every individual has a stake in the quality of the social environment on which its survival depends” (Flack and de Waal 2000, p. 14). However, in spite of the potential adaptive benefits of cooperation, there is a significant obstacle to the evolution of cooperative dispositions, namely, the conflicts of interest that inevitably occur within cooperative groups.

As expressed by the evolutionary biologist, Alexander (1987), “agreement seems to be universal...that moral (and ethical) questions and problems arise because of conflicts of interest; I have never found an author who disagrees. If there were not conflicts of interest among people and societies it is difficult to see how concepts of right and wrong, ethics and morality, and selfishness and altruism could ever have arisen” (p. 3). Conflicts of interest give rise to moral dilemmas that, if not resolved in cooperative ways, can diminish the reproductive success of all members of a group.

The anthropologist Boehm (2000) has argued that the central adaptive problems that moral instincts evolved to solve stemmed from “competitive dispositions to dominance” and the social conflicts they produced (p. 97). “Morality is the human invention that addresses such problems, and it is based very heavily upon ancestral dispositions. These were the raw materials, out of which moral communities were forged” (p. 97). According to Boehm, “morality is based heavily on social pressure, punishment, and other kinds of direct social manipulation” (p. 82), and the most significant sources of morality are instincts that induce individuals to obey the social norms of their groups and resist the temptation to dominate others. When members of groups succumb to the temptation to resolve conflicts of interest in selfish ways, it disrupts the cooperative order of the group and prevents everyone, including the cheaters, from reaping the benefits of cooperative exchanges.

Origins of Instincts to Behave in Altruistic and Group-Upholding Ways

It is much easier for evolutionary theorists to explain how dispositions to induce others to behave altruistically could have evolved than to explain how individuals acquired instincts to behave altruistically themselves. How could altruistic instincts have been selected if they decreased altruists’ chances of surviving and reproducing? This problem plagued Darwin (1874), who considered evidence of altruism potentially fatal to his theory. Modern evolutionary theorists have offered three main answers to this question: that altruism can evolve through kin selection, group selection, and sexual selection.

Kin Selection

Although Darwin (1874) focused most extensively on the possibility that altruistic instincts could evolve through group selection (see below), he briefly entertained the idea that even if altruistic members of groups were less likely to survive and to reproduce than selfish members of their groups were, their “tribe would still include their blood-relations” who could pass their altruistic traits on to future generations. Darwin did not fully appreciate the significance of this insight because he did not understand that blood relatives may share genes that code for altruism.

Armed with knowledge that genes are the primary unit of inheritance, Hamilton (1964) recognized that individuals can propagate their genes in two ways: (a) directly, by behaving in ways that increase their reproductive success, and (b) indirectly, by behaving in ways that increase the reproductive success of kin who possess replicas of their genes. This insight enabled Hamilton to predict that mental mechanisms that induce individuals to behave altruistically could evolve when the genetic costs to them (C) were less than the genetic benefits to recipients (B), multiplied by their degree of relatedness (r) – conditions captured in what came to be called Hamilton’s rule: $C < Br$ (also formulated as $Br > C$). The forms of altruism evoked by kin-selected mental mechanisms are most clearly exemplified by the sacrifices parents make for their offspring

($r = 0.5$), but they also extend to other blood relatives, such as brothers and sisters ($r = 0.5$), nephews, and nieces ($r = 0.25$).

Hamilton's rule implies that, all else equal, individuals will favor themselves ($r = 1$) and their relatives such as sons, daughters, and siblings who are most likely to share the genes that code for altruism; it does not imply that individuals will allocate their altruism to others in proportion to their degree of relatedness. Hamilton's rule implies that individuals will be most strongly disposed to help their relatives when the costs of helping them are low and the benefits the helpers receive are high and that helpers will be more prone to make sacrifices for relatives who possess high reproductive potential than for those who possess low reproductive potential. Researchers have amassed a great deal of evidence that humans and other animals behave in accordance with Hamilton's rule.

Triggering Kin-Selected Altruistic Instincts

In order for animals to propagate replicas of their genes in accordance with Hamilton's rule, they must be able to distinguish kin from non-kin and estimate the degree of to which they are related to them. Animals are not able to perceive their degree of relatedness to others directly, so they must derive inferences about genetic relatedness from kinship cues such as how similar others are to them (e.g., in appearance and odor), how familiar they are, and how close to them they reside (proximity). Because non-related members of groups may possess such cues, animals may end up helping those who look and act like their kin, thus contributing little or nothing to the propagation of their genes. Altruistic instincts probably originated as maternal (and in some species paternal) instincts, then were generalized in species such as our own to siblings, more distant relatives, and members of in-groups who looked and acted like kin.

Mental Mechanisms and Emotions Supporting Kin-Selected Altruistic Instincts

Triggers that induce humans and other animals to behave altruistically activate mediating mental mechanisms that affect their emotional and

cognitive states. Although the mental mechanisms that induce animals to help their kin (and those who resemble their kin) are designed in different ways in different species, research suggests that there are significant commonalities across mammals in the ways in which they operate. For example, these mental mechanisms appear to be regulated by hormones such as oxytocin, vasopressin, prolactin, and endogenous opioids, and they appear to generate psychological experiences of attachment, commitment, and love (Brown and Brown 2006).

Sympathy and Empathy

Because kinship equates to genetic similarity, it is not surprising from the perspective of evolutionary theory that people tend to identify with their relatives, to empathize with them, and to sympathize with them when they are in distress. de Waal (2008) has reviewed research demonstrating that empathy is evoked by kinship cues such as "similarity, familiarity, social closeness, and positive experience with the other" and that human "subjects empathize with a confederate's pleasure or distress if they perceive the relationship as cooperative" (p. 16). de Waal cites research showing that "seeing the pain of a cooperative confederate activates pain-related brain areas, but seeing the pain of an unfair confederate activates reward-related areas, at least in men." de Waal concludes that "the empathy mechanism is biased the way evolutionary theory would predict. Empathy is (a) activated in relation to those with whom one has a close or positive relationship, and (b) suppressed, or even turned into Schadenfreude, in relation to strangers and defectors."

de Waal summarizes his account of the evolution of empathy as follows:

Empathy covers all the ways in which one individual's emotional state affects another's, with simple mechanisms at its core and more complex mechanisms and perspective-taking abilities at its outer layers. Because of the layered nature of the capacities involved, we speak of the Russian doll model, in which higher cognitive levels of empathy build upon a firm, hard-wired basis. ... The claim is not that [this basis] by itself explains [all forms of empathy], but that it underpins ... cognitively more advanced forms ..., and serves to motivate behavioral outcomes. (p. 11)

According to Moll et al. (2008), “preliminary functional imaging results in normal subjects point to the involvement of the anterior PFC [pre-frontal cortex], the dorsolateral PFC, the OFC [orbitofrontal cortices], the anterior insula, and the anterior temporal cortex” (pp. 15–16) in the production of feelings of sympathy, pity, and compassion.

Group Selection

Contemplating the problem that altruism presented for his theory, Darwin (1874) considered the possibility that altruistic instincts that reduced the fitness of individuals could evolve if they increased the fitness of other altruistic members of their groups. If altruistic groups outcompeted selfish groups, then altruism could evolve through group selection – a process that selects traits that benefit groups even though they may be costly to individual members of the groups. However, Darwin immediately saw a problem with this idea, namely, that even if altruistic groups outcompeted selfish groups, the selfish members of altruistic groups would fare better than their altruistic cohorts, eventually driving them and their altruistic traits into extinction.

Although most contemporary evolutionary theorists are wary of the idea that altruism could have evolved through group selection, they acknowledge that it is possible under ideal conditions, which, according to some theorists were met during the evolution of the human species. In a prominent defense of group selection, Sober and Wilson (1998) identified five conditions under which altruism could evolve in a population even though it decreased within altruistic groups: (a) there are many groups in the population, (b) the groups contain different proportions of altruistic and selfish individuals, (c) the groups containing high proportions of altruists are more fit than selfish groups are, (d) altruistic and selfish groups compete against one another and form new groups, and (e) the fitness benefits to altruistic groups are greater than the fitness benefits to selfish individuals within the groups. Sober and Wilson suggested that when humans evolved, altruistic groups outcompeted more selfish groups, grew in size, and reconstituted themselves

before within-group selection for selfishness transformed the groups. In recent years, several eminent evolutionary biologists have endorsed the idea that altruism can evolve through group selection.

Many studies have found that people are willing to sacrifice their own interests to promote the collective interests of their groups. Perhaps the most striking examples stem from the behavior of soldiers during battle. As pointed out by Brown and Brown (2006), the US Army Field Manual contains the following passage, “while patriotism and sense of purpose will get American soldiers to the battlefield, the soldiers’ own accounts (and many systematic studies) testify that what keep them there amid the fear of death and mutilation is, above all, their loyalty to their fellow soldiers” (p. 38).

A group of evolutionary theorists has suggested that instincts to uphold large culturally defined groups evolved later than, and through a different form of group selection from instincts to help friends, relatives, and members of smaller in-groups. For example, Richerson and Boyd (2005) suggested that “tribal instincts” evolved relatively recently in the human species through cultural group selection. According to Richerson and Boyd (2005), tribal instincts “are laid on top of more ancient social instincts rooted in kin selection and reciprocal altruism” (p. 191), which causes humans to be “simultaneously committed to tribes, family, and self, even though our simultaneous and conflicting commitments very often cause us...great anguish” (p. 191). Richerson and Boyd view tribal instincts as analogous to Chomskyan linguists’ “principles and parameters . . . of language. . . . The innate principles furnish people with basic predispositions, emotional capacities, and social skills that are implemented in practice through highly variable cultural institutions, the parameters” (p. 191).

The sometimes acrimonious exchanges between evolutionary theorists who have argued for and against group selection are fueled by the different perspectives from which they view evolution. Several biologists have demonstrated that although models of group selection and models of kin selection are formulated in different ways,

they are mathematically equivalent. The essence of both models lies in the idea that genes that dispose a unit of selection to behave altruistically – whether this unit be individuals, families, or groups – can evolve when the altruistic behaviors have the ultimate effect of increasing the frequency of altruistic genes in the population.

Triggering Group-Selected Altruistic Instincts

The basic triggers for group-upholding altruistic instincts are cues to shared group membership. Although it might seem that humans would be evolved to identify with groups that are defined in terms of features such as race and physical appearance, and to sustain such group identifications throughout their lives, social psychologists have found that humans tend to be more flexible. For example, studies have found that individuals who are assigned to groups on an arbitrary basis such as whether they had blue eyes or brown eyes or whether they preferred one form of abstract art or another quickly identify with such groups and favor them when they distribute resources.

Mental Mechanisms and Emotions Supporting Group-Upholding Altruistic Instincts

According to Richerson and Boyd (2001), “we are adapted to living in tribes, and the social institutions of tribes elicit strong – sometimes fanatical – commitment” (p. 215). Social psychologists have attributed the feelings of solidarity that emerge in groups to people’s tendency to identify with in-groups and incorporate “social identities” into their self-concepts.

Sexual Selection

The third way in which altruistic instincts (and other moral instincts) can evolve is through sexual selection. Darwin opened the door to understanding the sexual selection of altruism by recognizing that adaptations that affect reproduction contribute as much – indeed in sexually reproducing species, often more – to the evolution of traits than adaptations that affect survival and that one of the ways in which individuals can increase their reproductive success is by sacrificing their interests for the sake of others. Altruistic traits that are a burden to survival can evolve through sexual

selection when they help individuals increase their reproductive success by attracting mates.

It is in the genetic interest of members of sexually reproducing species to select mates who (a) possess “good genes” that they can pass on to their offspring and (b) are disposed to help them and their offspring. One of the ways in which animals advertise that they possess good genes is by demonstrating that they are able to survive even though they possess a biologically altruistic “handicap” that induces them to make sacrifices for the sake of others. Altruistic behaviors constitute costly signals that advertise that the individuals who possess them are fit enough to survive in spite of them. Although studies on mate choice in humans have featured sex differences in the qualities that appeal to potential mates, members of both sexes rank altruistic qualities at or near the top of their lists.

Triggering Sexually Selected Altruistic Instincts

The primary triggers for sexually selected altruistic instincts are cues that signal the availability of attractive mates with high reproductive potential. Although we might expect the individuals doing the choosing to favor potential mates who signal that they are willing and able to help them and their offspring, individuals also may select mates who display a willingness to help a wider range of recipients, because such behaviors may signal that potential mates possess good genes and high social potential.

Mental Mechanisms and Emotions Supporting Sexually Selected Altruistic Instincts

It seems plausible that sexual selection played some role in the design of mental mechanisms that induce humans to experience feelings of romantic love. According to Fessler and Haley (2003), “a number of investigators...have suggested that some emotions can be understood as mechanisms designed to commit people to behavior that yields long-term payoffs, thus overcoming the temptation for short-term defection. Romantic love, a universal human emotion that underpins pair bonding...appears to be such a mechanism” (p. 10). When individuals are in love, they are motivated to impress their lovers,

to assist them, and to bring them gifts. Neuroscientists have found that feelings of love are correlated with the activation of the ventral tegmental and caudate nuclei of the brain (areas associated with experiences of pleasure), the production of neurochemicals such as dopamine, and the inhibition of neurochemicals such as serotonin.

An Integrative Account of the Evolution of Emotional Sources of Altruism

Brown and Brown (2006) have advanced an account of the evolution of altruism called selective investment theory that integrates other theoretical approaches. The central principle of selective investment theory is that individuals are instinctually disposed to help those with whom they share fitness interdependence. Brown and Brown (2006) review a large number of studies that support their claim that mental mechanisms have evolved in many species that induce them to form emotionally based social bonds with mates, offspring, friends, members of in-groups, and other individuals or groups on whom their fitness is dependent and that these bonds dispose them to treat these recipients altruistically. Selective investment theory postulates that the key to understanding the evolution of altruism lies less in determining whether altruists and recipients share genes or whether they pay one another back than in determining “the direction and magnitude of the correlation between the reproductive success of potential altruists and their recipients” (p. 9).

Origins of Instincts to Respect Authority

In addition to believing that it is right to behave altruistically and to uphold their groups, people from all cultures believe that it is right to respect legitimate authority and to obey rules that uphold the social orders of their groups. Instincts to respect authority probably originated in social species as elaborations of deferential instincts that upheld dominance hierarchies. Deferential instincts induce members of groups to avoid punishment from those who are more powerful than

they are and to accept subordinate positions until they are able to garner enough power to assume more dominant positions in their groups.

In addition to preserving subordinate group members' safety and physical well-being, deferential instincts induce subordinate members to uphold social orders that ultimately contribute to their fitness: “Low-ranking individuals are not simply dominated or exploited; they typically benefit from protection, advice, leadership, and intervention in disputes” (Haslam 1997, p. 300). Dominance hierarchies structure social orders in ways that benefit all members of groups, even if the benefits are distributed unevenly. Well-organized, cohesive groups tend to fare better than poorly organized groups in conflicts with other groups.

According to Haslam (1997), “there appear to be clear continuities between humans and non-human primates regarding the realization and representation of dominance” (p. 304) and, by implication, the realization and representation of instincts to respect authority. Deferential instincts evolved in humans in essentially the same ways in which they evolved in other primates, even though humans define dominance and authority in significantly more complex ways than other primates do and belong to a larger number of groups that are organized in a greater variety of ways. Primitive brain structures similar to those possessed by other primates dispose humans to behave in primitively deferential ways in conditions in which these forms of conduct increased the fitness of early humans. However, in contrast to other primates, humans also possess more sophisticated brain structures that endow them with the capacity to engage in complex forms of abstract and reflective thought and to communicate through symbolic language. The primitive and later-evolved brain structures communicate with each other, which affects the ways in which humans defer to and respect authority.

Triggering Deferential Instincts

Like other animals, humans who are faced with conflicts of interest evaluate the power and status of their opponents and select their strategies accordingly, respecting the authority of those

who have the power to defeat them and those they admire and dominating those who are weaker and of lower status than they are. However, humans are exposed to many more types of authority than other primates are. Although deferential instincts may be triggered by anyone identified as an authority, and even by the rules and norms of groups, humans tend to be more discriminating than other primates in deciding which authorities to obey.

Mental Mechanisms and Emotions Supporting Deferential Instincts

Evidence suggests that instincts to obey authority may be mediated by two types of qualitatively distinct emotions – (a) fear and insecurity and (b) admiration and awe. Fear is evoked by threatening stimuli such as powerful adversaries, whereas feelings of admiration and awe are evoked by accomplished people of high status. Fear is mediated by the autonomic nervous system and primitive brain mechanisms, such as the amygdale, interacting with interpretive mechanisms in the prefrontal cortex. According to Moll et al. (2008), “the neuroanatomy of awe is still obscure” (p. 16). Fear disposes individuals to respect authority in order to avoid punishment, whereas awe and admiration dispose people to make sacrifices for those they “worship” and to curry their favor. Different mixtures of fear and awe may engender different kinds of moral instincts. A spate of research has found that hormones such as androgen and serotonin play an important role in the activation of deferential instincts (Cummins 2005).

Origins of Instincts to Behave Fairly

Social animals induce members of their groups to treat them in fitness-increasing ways by rewarding those who benefit them (and/or their relatives) and punishing those who harm them. Animals that behave in these ways often are motivated to “get even,” which entails behaving fairly. With respect to primates, de Waal and Brosnan (2006) have suggested that “the squaring of accounts in the negative domain. . .may represent a precursor to

human justice, since justice can be viewed as a transformation of the urge for revenge, euphemized as retribution, in order to control and regulate behavior” (p. 88). In the positive domain, “the memory of a received service, such as grooming, induces a positive attitude toward the same individual, a psychological mechanism described as “gratitude” by Trivers” (p. 93).

Game theory research on the evolution of social strategies has demonstrated that individuals who invoke unfair strategies against one another in social exchanges tend to fare more poorly than individuals who invoke fairer strategies. Investigators have found that, in appropriate conditions, fair strategies such as tit for tat and firm but fair outcompete selfish strategies such as All-D [always defect] and therefore evolve. Fair strategies tend to pay off better than unfair strategies because it is in the adaptive interest of members of groups to ensure that cheaters do not prosper. Group members may reinforce fairness by getting even, rewarding those who behave fairly and punishing those who behave unfairly, selecting fair individuals as exchange partners and rejecting or ostracizing unfair individuals, and enhancing the reputation and social status of fair partners and turning others against unfair partners.

Triggering Instincts to Behave Fairly

Evolutionary theorists expect instincts to behave fairly to be triggered in contexts in which behaving fairly paid off better biologically than behaving unfairly did in the environments in which the animals in question evolved, such as contexts that involve repeated social exchanges between members of cooperative groups. These instincts are expected to be sensitive to cues that signal positive and negative consequences of behaving fairly, such as the probability that one will encounter an exchange partner in the future, exchange partners’ willingness and ability to reward fair behaviors and punish unfair behaviors, and the presence of an audience. Individuals are expected to be more strongly disposed to treat members of their in-groups fairly than they are to treat strangers, partners in one-shot exchanges, and members of out-groups fairly. In contrast to deferential instincts, which tend to be activated in relations

between dominant and subordinate members of groups, and in contrast to altruistic instincts, which tend to be activated in relations among friends, relatives, and loved ones, instincts to behave fairly tend to be activated in economic exchanges among equals. Evolutionary psychologists have pointed out that friends and loved ones rarely engage in tit-for-tat-like forms of reciprocity and that they normally are willing to support one another over long periods of time without any expectation of immediate returns. Indeed, people often feel offended when their friends adopt an “exchange orientation” and offer to pay them back.

Mental Mechanisms and Emotions Supporting Instincts to Behave Fairly

Some evolutionary psychologists have asserted that calculating the value of the goods and services that exchange partners give and receive, comparing them, and evaluating them in terms of an appropriate standard of fairness require sophisticated mental abilities that only humans may possess. However, other evolutionary theorists have disagreed, arguing that a sense of fairness may be mediated by less sophisticated mental abilities. In support of the latter position, Brosnan and de Waal (2003) found that capuchin monkeys that were offered a relatively undesirable reward for performing a task (a cucumber) after observing other monkeys receiving a more highly valued reward (a grape) got angry, refused to accept the less desirable reward, and even threw it away. The observers’ anger was intensified when the other monkeys did not have to work for the reward. Brosnan and de Waal (2003) concluded that “capuchin monkeys thus seem to measure reward in relative terms, comparing their own rewards with those available and their own efforts with those of others” (p. 48).

A suite of emotions has evolved to support instincts to behave fairly and through such behaviors to uphold the cooperative orders of groups (Fessler and Haley 2003; Trivers 2006). One set of emotions, which includes feelings of gratitude and a sense of indebtedness and guilt, motivates individuals to even the score by paying their debts and righting the wrongs they have perpetrated. Another set of emotions, which includes anger

and righteous indignation, motivates individuals to induce others to behave fairly. Forgiveness motivates individuals to renew damaged social exchanges. Researchers have begun to identify triggers for these emotions, to map the design of the mental mechanisms that support them, and to identify the areas in the brain that induce them.

Gratitude

In a review of the research on gratitude, McCullough et al. (2008) suggested that gratitude evolved “to stimulate not only direct reciprocal altruism, but also “upstream reciprocity:” passing benefits on to third parties instead of returning benefits to one’s benefactors” (p. 283). According to Moll et al. (2008), people feel gratitude when they experience positive outcomes that they attribute to the agency of a person who intended to improve their well-being. Gratitude engenders attachment to benefactors and the motivation to pay them back. “Activated brain regions include the ventral striatum, the OFC, and the anterior cingulate cortex” (p. 16). McCullough et al. (2008) have found that feelings of gratitude are affected by the value of benefits, the costs of giving, the perceived intentions of the benefactor, and the extent to which the beneficial behaviors are viewed as voluntary, expected, and normative. In contrast to feelings of indebtedness, which people experience as a negative state that motivates them to redress perceived inequities, people experience gratitude as a positive state that motivates them not only to help those who benefited them but also to help third parties.

Guilt

Members of cooperative groups inevitably make mistakes and treat others unfairly. Feelings of guilt evolved to motivate people to uphold the social norms of their groups and avoid punishment from others by making amends, righting the wrongs they perpetrated, repairing damaged social relations, and getting mutually beneficial cooperative relations back on track. Social psychologists have found that people feel guilty when they feel responsible for causing those to whom they feel attached to experience bad outcomes, especially when their behaviors violate moral norms. Theorists disagree about the emotional

origins of guilt. Some assert that it is rooted in fear, whereas others assert it is rooted in sadness. According to Moll et al. (2008), “recent neuroimaging data showed the involvement of the anterior PFC, the anterior temporal cortex, the insula, the anterior cingulate cortex, and the STS [superior temporal sulcus] regions in guilt experience” (p. 13).

Indignation and Vindictiveness

Being treated unfairly and observing others being treated unfairly may trigger feelings of indignation and vindictiveness, which may motivate individuals to right the wrong by punishing those who have behaved in unfair ways. Inasmuch as getting even entails righting a wrong, it entails behaving fairly. In addition, the anticipation of punishment for behaving unfairly motivates individuals to treat others fairly. According to Moll et al. (2008), people feel indignant when they observe others intentionally violating norms: “Indignation relies on . . . engagement of aggressiveness, following an observation of . . . bad outcomes to the self or a third party. . . and “evokes activation of the OFC. . . the anterior PFC, anterior insula, and anterior cingulate cortex” (p. 15).

Research has revealed that feelings of vindictiveness and associated motives to take revenge stem from different mental mechanisms from those that produce feelings of moral indignation (McCullough 2008). Areas of the brain such as the left prefrontal cortex and caudate nucleus that are associated with the pursuit of rewards light up when people feel vengeful, but areas of the brain such as the nucleus accumbens that are associated with feelings of satisfaction light up when people take revenge or learn that those who have treated them unfairly have been punished. According to McCullough (2008), “revenge pays neurochemical dividends. . . Natural selection’s logic here seems pretty easy to comprehend: by paying us back with pleasure, our brains ensure that we’ll go to the trouble of seeking the social advantages that come from returning harm for harm.”

Forgiveness

Although members of all human groups right wrongs and get even by punishing those who treat them and other members of their groups

unfairly, this strategy runs the danger of disrupting mutually beneficial cooperative relations and inviting reciprocally punitive tit-for-tat types of reactions that lead to fitness-reducing blood feuds. To counteract this danger, dispositions have evolved that dispose members of groups to repair damaged social relations by forgiving those who have trespassed against them. Strictly speaking, forgiveness does not support the disposition to treat others fairly unless it is invoked to even the score with those who have forgiven one in the past; however, forgiveness supports fair systems of cooperative exchange by helping to get them back on track after they have been derailed.

McCullough (2008) has reviewed research demonstrating that forgiveness constitutes a culturally universal social instinct that mediates reconciliation in humans, chimpanzees, and other primates. According to McCullough (2008), forgiveness is activated when individuals (a) feel close to and empathize with those who have wronged them, (b) are motivated to guard against the loss of beneficial relationships, (c) are confident that the wrongdoers will not harm them again, and (d) believe that forgiving the wrongdoers will increase their security. When making decisions about whether or not to forgive those who have trespassed against them, people attempt to determine whether the wrongdoers intended to harm them, could have avoided harming them, feel regretful about the harm they perpetrated, and are likely to repeat the offense. Being wronged activates stress hormones such as cortisol that generate unpleasant feelings of anger and anxiety that victims can relieve by forgiving those who wronged them or seeking revenge against them. The neurochemistry of forgiveness involves mechanisms that reduce the stress engendered by ongoing social conflicts.

Origins of Instincts to Uphold Purity

It is in the adaptive interest of group members to ensure that their environments, including other members of their groups, do not contaminate them and cause them to get sick. Rozin et al. (2000) have found that stimuli associated with the risk of harm due to germs, such as bodily

fluids, dead animals, garbage, and rancid smells, evoke feelings of disgust and that this emotion tends to activate negative moral instincts in humans. Rozin et al. (2000) have pointed out that sexual acts involve the exchange of bodily fluids and that sexual prohibitions such as those associated with menstruation, anal sex, and bestiality are often based on ideas of pollution and feelings of disgust. According to Moll et al. (2008), “the neural representations of disgust ... include the anterior insula, the anterior cingulate and temporal cortices, the basal ganglia, the amygdala, and the OFC” (p. 15).

Rozin et al. (2000) have suggested that in humans, moral disgust is an “embodiment” of nonmoral disgust that originated in digestive repulsion. As with other forms of disgust, the adaptive function of moral disgust is to motivate people to avoid potentially noxious stimuli, whether physical or social in nature. It is in the adaptive interest of members of groups to steer clear of those who emit signs of impurity and by implication to behave in pure ways themselves. “Cleanliness is next to godliness.” Rozin et al. (2000) also have suggested that instinctive reactions to physical impurity and purity may be generalized by humans into ideas about spiritual impurity and purity. People tend to view acts that corrupt people as immoral and pureness of spirit as moral. In support of these ideas, research has revealed that disgusting events that have little to do with morality can intensify moral instincts. For example, investigators have found that the harshness of people’s moral judgments is intensified when they are in a filthy, messy room.

Imperfections in the Design of Psychological Mechanisms and the Role of Manipulation in the Activation and Evolution of Moral Instincts

The mental mechanisms that give rise to and regulate moral instincts are not perfect, and imperfections in their design may induce individuals to behave in ways that render their conduct more or less moral than the adaptive forms of conduct that

mediated the evolution of the mechanisms. For example, instincts to avoid contamination may induce individuals to purify themselves in religious rituals and to uphold food prohibitions that foster or diminish their fitness. Instincts to defer to authority may induce people to follow the orders of cult leaders, abide by the dictates of gods, and obey arbitrary rules. Instincts to help kin may be triggered by individuals who look and act like kin, which may contribute little or nothing to the propagation of their genes.

Members of most social species engage in strategic forms of interaction in which they attempt to manipulate one another into behaving in ways that increase their fitness by preying on imperfections in the mental mechanisms that regulate their moral instincts. Like cuckoo birds that trick neighboring birds into suffering the costs of sitting on their eggs, humans attempt to manipulate others into behaving morally by acting like they are their kin, by misrepresenting their value as mates, by acting more dominant and pure than they really are, by exaggerating the value of the assistance they have proffered to them, by persuading others that altruism pays off, and so on. However, because it is in the biological interest of recipients of these overtures to detect and counteract such manipulations, countervailing mechanisms have evolved. In effect, manipulative mental mechanisms have selected increasingly effective countervailing mechanisms, which have selected increasingly effective manipulative mechanisms, and so on in an arm race manner that has caused members of many social species to develop highly sophisticated social strategies. Mutual manipulation probably played a key role in the evolution of the human brain as well as the evolution of moral judgments, moral beliefs, and moral norms (Krebs 2011).

Summing up, people from all cultures are naturally inclined to behave in altruistic, group-upholding, deferential, fair, and pure ways, and people from all cultures consider these forms of conduct right and their opposites wrong. Instincts to behave in ways that uphold universal moral norms are triggered by particular stimuli and are mediated by mental mechanisms that produce emotional experiences such as love, sympathy,

gratitude, and indignation. Although such emotions have been called “moral emotions” because they give rise to forms of conduct that people consider moral, they may be evoked by nonmoral triggers and fail to be accompanied by attributions of right and wrong. For example, people may sympathize with a friend who has been diagnosed with cancer or killed by lightning without feeling that anyone has committed a moral transgression, and people may feel gratitude when they experience a stroke of good luck without feeling that they deserve the positive outcome.

Explaining how humans acquired instincts to behave in ways that they consider moral does not equate to explaining how humans acquired the mental mechanisms that induce them to feel or to sense that these forms of conduct are moral. To fully account for the evolution of moral instincts, evolutionary theorists have attempted to explain how the mental mechanisms that give rise to a sense of morality, or more exactly, to the moral senses, evolved (Krebs 2011).

Origins of a Sense of Morality

All normal human beings possess a sense of morality that induces them to think and feel that certain phenomena are right and wrong, good and bad, and virtuous and vicious. All people make prescriptive and prohibitive moral judgments about how they and others ought and ought not to behave; and all people pass judgment on the moral and immoral behaviors of others. Research has indicated that children distinguish between rules that uphold moral orders and other kinds of rules very early in their lives and that they believe it is significantly more important to uphold the former than to uphold the latter. As expressed by Cummins (2005), “children are significantly better at detecting violations of rules in the social domain, such as those dealing with permissions, prohibitions, promises, obligations, and warnings, than they are at detecting violations of rules in other domains” (p. 698). Children distinguish between moral rules and rules that uphold social conventions by the time they are 3 years old. “When asked to test compliance with social

rules, 3-year-olds have been found to spontaneously seek out potential rule violations just as adults do. . . ., readily distinguish rule-violating behavior from compliant behavior. . . The average 3-year-old appears to have as firm a grasp on the implications of socially prescriptive rules as the average adult” (Cummins 2005, p. 689).

Emotional and Rational Aspects of a Sense of Morality

There is a long-standing debate among scholars about the extent to which people derive moral judgments from emotional and rational mental processes (Denton and Krebs 2016). In one camp, philosophers such as Kant and cognitive-developmental psychologists such as Lawrence Kohlberg have argued that all moral judgments stem from reason and that judgments that stem from emotional sources do not qualify as moral. In the other camp, philosophers such as Hume and social psychologists such as Haidt (2001) have asserted that reason is the “slave of the passions” and that moral judgments are primarily manifestations of emotional states.

Some theorists have attempted to resolve this dispute by demonstrating that two sets of mental mechanisms have evolved in humans – one that induces them to make moral judgments in emotional ways and the other that induces them to make moral judgments in more rational ways. According to Haidt (2001), “The affective system has primacy in every sense: It came first in phylogeny, it emerges first in ontogeny, it is triggered more quickly in real-time judgments, and it is more powerful and irrevocable when the two systems yield conflicting judgments” (p. 819).

In one line of research that has supported dual-process models of moral judgment, neuroscientists have used techniques such as fMRI to assess brain activity as participants make decisions about hypothetical moral problems such as those that are contained in trolley dilemmas. For example, Greene and his colleagues (see Greene 2013) asked participants to make moral judgments about two versions of a dilemma that involved a trolley heading down a track containing five people whom it is destined to kill. In the first version, called the “switch” dilemma, participants are

asked to decide whether they should pull a switch that would cause the trolley to be redirected onto a different track containing only one person. In the second version, called the “footbridge” dilemma, participants are asked to decide whether to push a large man off a footbridge onto the track to stop the trolley. Consistent with the findings of other investigators, Greene and his colleagues found that most participants said that it would be right to pull the switch but wrong to push the large man onto the tracks. In support of the idea that different mental mechanisms mediated this difference in moral judgment, Greene and his colleagues observed an increase in activity in regions of the brain mediating rational moral judgments when participants responded to the “switch” dilemma and an increase in activity in regions of the brain mediating emotional judgments when participants responded to the “footbridge” dilemma. Greene (2013) argued that in contrast to the position advanced by philosophers such as Kant, these findings indicated that emotional reactions induce people to make categorical, deontological moral judgments (e.g., it is never right to violate people’s right to life) and rational reactions induce people to make utilitarian judgments (e.g., it is right to sacrifice the life of one person to save five). However, some philosophers have disagreed with this conclusion.

In another line of research supporting dual-process models of moral judgment, investigators have examined the effects of damage to areas of the brain that mediate emotional reactions to moral issues. In a classic set of studies, the neuroscientist Damasio (1994) found that although patients with damage to the ventromedial area of the prefrontal cortex – an area that mediates emotional processes – made normal kinds of moral judgments to hypothetical moral dilemmas, they behaved in highly immoral ways in their everyday lives. Damasio (1994) concluded that the deficiencies in real-life moral judgment displayed by these patients stem from problems with the activation of moral emotions. People with injuries to their ventromedial prefrontal cortex are able to understand the difference between right and wrong in principle, but they do not *feel* the difference, because they do not experience moral instincts that give

rise to emotions such as shame, guilt, gratitude, and moral outrage in the same way that normal people do.

Denton and Krebs (2016) advanced an “evolutionary-developmental” explanation for the findings from research supporting dual-process models of moral judgment, suggesting that early-evolved brain mechanisms that humans share with other primates give rise to moral emotions; later-evolved brain mechanisms give rise to sophisticated forms of moral reasoning; and the latter increase in power in humans as they develop throughout their life span. According to Denton, “The basic moral emotions produced by primitive brain structures work quite well in enabling social species such as chimpanzees that live in relatively small groups and form relatively simple societies to coordinate their efforts in mutually beneficial ways . . . [and] they also work reasonably well for modern humans in social contexts that are similar to those experienced by chimpanzees and early humans, such as those that include family, friends, and small in-groups. However, because humans are the only species that evolved neocortices capable of performing sophisticated forms of moral reasoning we can safely infer that, early humans experienced adaptive social problems different from those experienced by other species. The high correlation between brain size and group size in social animals . . . suggests that adaptive problems related to complex systems of cooperation and social relations among members of large groups may have played an important role in the evolution of the neocortex.”

The Moral Senses

Although all aspects of a sense of morality induce people to think and feel that certain phenomena are right and wrong, different aspects induce people to experience different kinds of moral sentiments and to make different kinds of moral judgments. Some moral sentiments pertain to one’s self and one’s behavior (e.g., guilt), whereas other moral sentiments pertain to other people and their behavior (e.g., righteous indignation). Some moral sentiments are imbued with positive thoughts and feelings (e.g., moral approbation), whereas others are imbued with negative thoughts

and feelings (e.g., moral disapprobation). Some moral sentiments are activated by thoughts and feelings about how people should and should not behave in the future (e.g., a sense of moral obligation), whereas other moral sentiments are activated by events that already have occurred (e.g., moral outrage). Moll et al. (2008) have suggested that “moral emotions might prove to be a key venue for understanding how phylogenetically old neural systems, such as the limbic system, were integrated with brain regions more recently shaped by evolution, such as the anterior PFC [prefrontal cortex], to produce moral judgment, moral reasoning, and behavior” (p. 17).

Origins of the Moral Senses

Although the basic adaptive function of all moral instincts is to induce individuals to uphold moral norms that support the social orders of their groups, different moral sentiments accomplish this in different ways. The function of some moral sentiments is to induce others to behave in moral ways (e.g., sentiments that induce individuals to approve of group-upholding, cooperative, and altruistic behaviors, to feel vengeful when members of their groups exploit them, and to experience feelings of righteous indignation when they observe third parties behaving unfairly). The function of other moral sentiments is to dispose the individuals who experience them to behave in moral ways (e.g., sentiments that engender feelings of moral obligation, sentiments that induce people to resist temptation, and sentiments that evoke feelings of guilt).

Origins of Moral Sentiments About Others

Moral sentiments triggered by the behavior of others probably originated in positive and negative emotional reactions to social behaviors that had good and bad effects on recipients' fitness and the fitness of their relatives, friends, and members of their in-groups. It is safe to assume that early humans liked being treated in kind, loyal, respectful, fair, and uncontaminated ways by others because these forms of conduct helped them survive, reproduce, and propagate their genes. On the

other hand, early humans surely disliked being treated in cruel, disloyal, disrespectful, unfair, and unclean ways, just as modern humans do. It also is safe to assume that positive reactions to being treated in fitness-increasing ways and observing one's relatives and friends being treated in these ways evoked a primitive evaluative sense that these forms of conduct were right and that the people who emitted them were good, whereas negative reactions to being treated in fitness-decreasing ways and observing one's friends and relatives being treated in these ways would have engendered the sense that these behaviors were wrong and that those responsible for perpetrating them were bad.

Origins of Sense of Moral Obligation

Darwin (1874) believed that the essence of morality lies in a sense of duty and that this sense is engendered by the activation of social instincts: “The imperious word ought seems merely to imply the consciousness of the existence of a rule of conduct, however it may have originated” (p. 112). In contrast to nonmoral feelings of duty, feelings of moral obligation pertain to shared standards of conduct that are prescribed by moral norms, supported by sanctions, and affect the welfare of members of one's group.

Origins of Conscience and a Sense of Guilt

Whereas a sense of moral obligation involves forward-looking motives to behave in moral ways, a guilty conscience involves backward-looking reactions to misdeeds that people have committed. When people's consciences bother them, they pass judgment on themselves. (Anticipatory feeling of guilt also may be evoked when people entertain the idea of committing immoral deeds.)

Darwin (1874) advanced an account of the evolution of conscience in which he suggested that satisfying a pressing but transient antisocial need that leaves a more enduring prosocial need unsatisfied induces people to feel that they made the wrong choice. Supporting such feelings, Darwin suggested that “man would be influenced in the highest degree by the wishes, approbation, and blame of his fellow-men,” and the “deep regard”

people feel for the “good opinion” of their fellows would cause them to regret their misdeeds and feel guilty about them (p. 106).

Findings from research on the development of conscience in children are consistent with expectations derived from a Darwinian framework. For example, in a review of the literature, Thompson et al. (2006) concluded that “one of the strong motivators for morally compliant behavior is the salient emotion that arises from cooperative and uncooperative conduct” (p. 277). “Conscience development has its origins in infancy, where the sanctions (and rewards) of adults in response to the child’s actions have emotional and behavioral consequences. . . experiences of approval and disapproval are important” (pp. 269–270). “Young children are motivated to cooperate with the expectations of parents to enjoy the positive affectionate relationship that they enjoy. Viewed in this light, the parent-child relationship in early childhood can be conceived of as the young child’s introduction into a relational system of reciprocity that supports moral conduct by sensitizing the child to the mutual obligations of close relationships” (p. 282). Moll et al. (2008) have found that guilt stems from “the blending of elementary subjective emotional experiences, which are ubiquitous in mammals, with emotional and cognitive mechanisms that are typically human” (p. 4).

Origins of a Sense of Justice

Trivers (1985) has asserted that “a sense of fairness has evolved in the human species as the standard against which to measure the behavior of other people, so as to guard against cheating in reciprocal relationships” (p. 388), and “such cheating is expected to generate strong emotional reactions, because unfair arrangements, repeated often, may exact a very strong cost in inclusive fitness” (Trivers 2006, p. 77). Evolutionary theory has no difficulty explaining why members of groups would feel that it is right for others to treat them fairly and wrong for others to treat them unfairly, but it is more challenging to explain how the sense that it is right for them to treat others fairly evolved. As expressed by Trivers (2006), “an attachment to fairness or justice is self-interested and we repeatedly see in life. . . that

victims of injustice feel the pain more strongly than do disinterested bystanders and far more than do the perpetrators” (p. 77).

Psychologists have amassed a great deal of evidence in support of self-serving biases in people’s sense of justice. For example, studies have found that people hold themselves to lower standards of fairness than they apply to others, underestimate how much they owe others and overestimate how much others owe them, overvalue the costs of giving to others and undervalue the benefits of receiving, and react less strongly to treating others unfairly than to being treated unfairly by others. Such biases notwithstanding, evolutionary theorists also expect constraints on self-serving biases in people’s sense of justice to evolve for much the same reasons that evolutionary game theorists expect unconditional selfishness to be a nonoptimal strategy in repeated interactions among members of groups. Indeed, some evolutionary psychologists have found that people’s sense of justice may, under some conditions, be biased in favor of others. For example, researchers have found that people may feel worse when they fail to repay their friends than they do when their friends fail to repay them.

The precursors to a sense of justice in other primates observed by investigators such as de Waal appear to be limited to positive and negative reactions to being treated fairly and unfairly by other members of their groups, and humans also display such reactions. However, in addition, humans may react strongly to the ways in which third parties are treated – a phenomenon that has been labeled “strong reciprocity.” As expressed by Wilson (1993), “our sense of justice. . . involves a desire to punish wrongdoers, even when we are not the victims, and that sense is a ‘spontaneous’ and ‘natural’ sentiment” (p. 40).

Conclusion

Although it may seem on the surface that evidence of moral instincts that induce humans and other animals to behave altruistically, to uphold their groups, to respect authority, to behave fairly, and to purify themselves is inconsistent with

evolutionary theory, on close examination it becomes clear that it is not. Instincts to behave in moral ways and instincts to make moral judgments have evolved because they help social animals survive, reproduce, and propagate their genes. Moral instincts induce social animals to sacrifice their short-term interests in order to achieve the long-term biological benefits they can obtain by upholding their groups and supporting those on whom their fitness is dependent. Moral instincts enable members of groups to reap the benefits of sociality and cooperation and to foster their fitness by resolving their conflicts of interest in mutually beneficial ways.

Moral Instincts and Morality

Demetra Themistocleous and Xenia Anastassiou-Hadjicharalambous
University of Nicosia, Nicosia, Cyprus

Synonyms

Gut feelings; Moral intuitionist theory; Moral intuitions

Definition

Moral instincts, or otherwise social intuitions, are unconscious abilities that differentiate between right and wrong actions.

Introduction

Since the advent of psychology, Bargh (1989) stated that people access substantial types of knowledge without phenomenological cognizance. According to Reber (1993), awareness and phenomenological cognizance are comparatively new concepts in comparison to other functions of the brain considered to be unconscious. Lately, some scientific disciplines such as evolutionary psychology and cognitive sciences proposed intuitionist approaches to human functioning (Klein 2003).

Long ago, gut feelings were considered unreasonable. Now, however, things have changed significantly, and often reasoning is considered needless (Cummins 2003). Certain theories, like

the moral intuitionist theories, emphasize people's sudden instinct reactions that they exhibit toward others. As per this view, the intuitive moral judgments are vital part of human moral behavior. These theories further vie that moral intuitive responses result from a person's inherent computational elements obtained from the evolutionary history of the human species and are shaped by the way people were raised in their culture.

Haidt (2001) proposed the “social intuitionist model” of moral functioning. The model suggests that social instincts are a fundamental and quick response that emerges to differentiate between rightness and wrongness without any cognizant of their source. Therefore, moral instincts may or may not be followed by rationale. The “social intuitionist model” was initiated from the data of specific set of scenarios that were designed to provoke repulsive behavior (Haidt et al. 1993). For instance, one scenario details consensual sexual intercourse between adult siblings who, although they both seek pleasure from their experience, decided that they will not do it again. Another scenario describes eating the family dog after it got hit by a car. A third scenario describes a man who bought chicken from the supermarket and cooked and ate it after masturbating on it. After participants were presented with these provoking, repulsive scenarios, they were asked whether the actions in the scenarios were right or wrong and indicated why. Participants were able to decide rightness or wrongness immediately. In contrast, after confronted with an opposite opinion claiming that although the scenarios seem disgusting, no harm could result from people's actions, the participants were unable to give a reason for their judgment. Haidt's “social intuitionist model” had been influential to other approaches followed afterward to support or reject the importance of instincts in moral judgments (Gigerenzer 2008).

Conclusion

Moral instincts are considered important in the study of morality in several aspects. Firstly,

people can differentiate between rightness and wrongness without any cognizant of their source and therefore can shape some moral judgments. Second, moral instincts revolve around the concept of unconscious inherent processes that are necessary for human functioning, and thus these processes lead to moral actions.

Moral Language Regulation

David S. Smith

Psychology, BPP University, London, UK

Definition

Recursive language evolved as a precursor to human value systems.

Introduction

In *The Descent of Man*, Charles Darwin identified a moral sense as the cornerstone of what it is to be human. He suggested that, to a social species, the evolution of an ethical brain was essential. This is because no interdependent tribe could succeed if immoral acts, like murder, were to become commonplace. Although the author goes on to claim differences in morality between humans and other animals are a matter of degrees, crucially he suggests only the former can regret actions. Moreover, only they can categorize them in terms of rightness or wrongness. Methods of policing have been observed in other species such as chimpanzees. Yet it seems only humans are able to construct formal moral frameworks, like legal systems, to regulate aspects of life that are not directly linked to reproductive fitness (e.g., obscenity, blasphemy, and copyright legislation). This exception to the general rule within nature suggests that moral systems are a recent adaptation.

Another trait considered distinctly human is the capacity for language. Other animals harbor elaborate communication systems enabling them to alert peers to environmental features, and in some instances, there is even evidence of them attaching distinct sounds to particular targets. For example, vervet monkeys have been found to

produce acoustically different alarm calls in the presence of different predators (Seafarh et al. 1980). Yet human language is thought to be remarkable because of its flexibility, i.e., the ability to combine symbols into understandable structures (Hauser et al. 2002). Humans appear to have been uniquely endowed with the recursive computational mechanisms required to create infinite combinations from a finite set of elements. It is this combinatorial property that has led to the emergence of these two capacities to be considered in parallel.

A Link Between Language and Morality

In addition to the recursive properties of language allowing humans to generate speech creatively, Poulshock (2006) reasons that they let humans moralize creatively. In as much as speakers can use terms to name an unlimited amount of concepts, the author argues they can also discuss them or catalogue them in terms of being positive or negative. People can moralize about cultural etiquette, or important contemporary concerns (e.g., current affairs or the use/abuse of modern technology), along with relatively inconsequential topics (e.g., if a comedian has gone too far). They can also moralize about events that are temporally displaced (e.g., dwelling on past events or considering future ones) or the consequences of things we may never do (e.g., “if I were to do X then Y will be the result”). What’s more, the author points out that speakers can use language to meta-moralize about the nature of morality itself and whether or not it is actually moral to moralize.

Even if nonspeaking animals were to have the cognitive apparatus required for constant reflection, Poulshock argues it is unlikely they would be able to share or enforce morality. For instance, he asks, how would a clan with limited linguistic resources share nuanced ethical judgments beyond approach and avoidance behavior (e.g., violence is acceptable when used for self-defense)? In the absence of language, or paralinguistic features, the author claims it would not be possible to share these values or communicate an

intricate social etiquette for others to abide by. Instead, the direct transference of beliefs and values is most easily achieved through oral or written means. Principles can then be supported by consensually agreed ethical frameworks which are shared within a given population.

Thus Poulshock hypothesizes the uniquely human property of language paved the way for the equally unique property of morality to be shared culturally or intergenerationally. Furthermore, he writes, a recursive communication system that is open to temporally and spatially displaced events can enforce moral behavior with linguistically encoded promises, threats, rewards, or punishments. The result is a socially constructed code which is capable of informing conduct, as well as providing individuals a criterion to evaluate others. On a microlevel, the ease of transmission means communities can establish their own unique information-sharing networks. Members can then be selectively raised or socialized to a specific moral tradition. The author cites the example of religious organizations promoting moral precepts through the use of language. For instance, the Deuteronomic tradition teaches followers to memorize commandments, verbally impart them to others, proselytize with nonbelievers, and record their values in the form of memes (e.g., paintings or signs). Accordingly, our language instinct has historically been treated as critical to the internalization and spread of a moral code.

Ergo Poulshock claims the evolution of language has allowed for members of a community to widen their influence to guide or manipulate the behavior of peers. Linguistically enabled morality lets individuals or groups benefit from cohesion and cooperation through cost-efficient means. It also eases the rapid communal good or bad marking of members, depending on their compliance. The second reason prompts another possible factor in the relationship between language and morality: formal or informal legal structures.

Knight (2008) studies this proposition in detail, theorizing language and the rule of law developed in tandem. Each is thought to stem from adaptations designed to enforce cooperation between strangers. So instead of viewing morality as a

product of language, he contends the two capacities are synonymous in evolutionary history. To illustrate this notion, he juxtaposes the lack of shared morality in primate societies, where conflict is physically resolved, with the self-governing egalitarianism of hunter-gatherer ones. The difference, he suggests, is that the latter are not bound to the same laws of signal operation that are limited to acts of the body. Instead, the advent of language has enabled them to signal in the abstract. This means that humans can utilize institutional beliefs (i.e., protocols) so that important behaviors such as sexual activity and competition can be regulated without conflict. To paraphrase Goodall (1982), this difference may be why human societies exhibit law with order, whereas chimp societies are run by order without law. The role of language in determining these conventions empowers human societies to transcend primate politics, where the key arbiter is dominance.

Boyd and Richardson (2009) also support the coevolution of language and moral structures. They argue that humanity's linguistically determined ability to set social norms is what led to cultural evolution, resulting in the beginning of distinct populations. Within each given group, the extent that conventional behaviors are adopted is influenced by the three Rs, i.e., the impact on reputation, the likelihood of reciprocation, and the possibility of retribution, if they go ignored. In a civilization comprised of small clans, the authors deduce that group-level cooperation would predict the attainment and survival of different communities. They argue that within social systems, where morality is reinforced by punishment or reward, reproductive success is determined by the extent an individual fits in with their community. Accordingly, mating competition would favor those with phenotypes supporting pro-social vs anti-social behavior. Zlatev (2014) adds that an adaptation allowing individuals to be continuously tracked is core to this paradigm. Hence a communication system based upon displacement is highly advantageous for enabling others to compare opinions on fellow group members. Reputations can be systematically enhanced or reduced based upon the extent

to which they deviate from ideals. He concludes that this led to the evolution of traits promoting pro-social behavior, like shame. This hypothesis is akin to Dunbar's (2004) gossip model, which claims one functional role of language is being able to identify individuals who reap benefits from a society they do not contribute to. In his framework, the benefits of being able to identify and share information about "free riders" are twofold. Firstly, speakers may be able to protect other group members from exploitation. Secondly, the spread of such a trait could deter those that wish to exploit them.

As well as the contrivance and enforcement of morals, Poulshock (2006) asserts another adaptive role for language is offering people a means to assess their behavior from its impact on others. Moreover, it lets group members make others privy to their own mental states. This bi-directional mind reading grants greater insight of moral relations than any closed communication system ever could. Similarly, Zlatev (2014) asserts that language and morality both emerged in tandem with capacities to share affective, perceptual, or reflective experiences, including joint attention and empathy. In addition, when met with convoluted circumstances, which can be expected in even the smallest communities, Poulshock (2006) argues oral and written exchanges support discussion and reconciliation. This is particularly common when an understanding of tensions requires third-level intentionality, i.e., knowing someone else who knows someone else who knows something (Dunbar 2004). Language can also be useful in instances where a trusted mediator can communicate an apology or peace offering on another's behalf: another scenario a closed system could not assist.

Moral Development

One way of testing a functional link between language and morality is to study the ontogeny of each trait. If a utility of language is the circulation of communal values, then both ought to emerge and develop simultaneously. However, research into this potential relationship is

constrained by the need for subjects to possess the language skills necessary to describe their moral considerations. Consequently, young children are generally not suitable for testing. This means the modest literature has tended towards theoretical discussions.

Poulshock (2006) suggests parallels in acquisition are commonsense, since an appreciation of complex issues requires the vocabulary to comprehend and discuss them. He cites examples of stumped language and moral development in neglected children, implying a critical period for both that may be owed to crossover modules. Further indirect evidence of a functional link is shown by linguistic analysis from Snow (1990), who analyzed transcripts of 51 h of caregiver and child interactions. At two and a half, she found children spent the most time talking about bad behavior, whereas at three and a half, it was more good behavior. Finally, at four and a half, she noticed they became focused on “should” or “should not” discussions. Based on this, Snow describes the ontogeny of moral sense as following a negotiation of the meaning of words and acts, predicting a correlation between linguistic and moral sophistication. Likewise, Hanfling (2003) advocates a connection, asserting that as children are introduced to concepts (e.g., bullying), they are also taught about their community’s judgments of them (i.e., it is wrong).

Combined, these studies present a consistent picture of language providing a means for parents or guardian to introduce and contextualize specific actions. Children’s moral maturation is then, by necessity, led by language. Its recursive and displaced properties are therefore critical to reinforcing schemas in instances when a behavior does not proceed the lesson. This does not necessarily suggest infants do not possess an innate sense of wrongness. Though it does suggest that the way concepts are first introduced to them goes some way toward determining how they are later regarded.

Conclusion

Humans are not only special in their capacity for language but also in their ability to design,

internalize, and enforce communal values. The key suggestion from the work cited above is that societies based on the collective codification of morality can only be achieved with a flexible means of expression. Unlike their closest evolutionary cousins, people can reason and reconcile with each other in the abstract and establish institutions plus communal values. In particular, the recursive aspect of language and the option to converse over events and people displaced in time and space are thought to play essential parts in regulating morality. A related avenue not touched here is the assumption that, in addition to facilitating moral codes, language facilitates immorality by making deception easier with the option to lie. Although as Poulshock (2006) deliberates, this does not contradict its role in enabling, extending, and maintaining morality.

Definition

Moral tribes refers to a specifically value-based dimension of tribalism, which is a set of behaviors and cognitive mechanisms that lead individuals to favor themselves and the groups to which they identify. Groups that identify with a set of interests and values distinct from another set of interests and values constitute differing moral tribes.

Introduction

Evolution by Darwinian natural selection appears to be an extremely selfish process by which individuals compete against other individuals in a contest for survival and reproduction. However, Hamilton (1964) showed, and Dawkins (1976) articulated, that “selfish genes” can lead to altruistic and cooperative behaviors at the level of individuals, especially if those individuals are kin and therefore share genes with each other. When individuals are not kin, it can still ultimately favor the helper to aid strangers if it is done under the assumption that the stranger will repay the favor, or reciprocate (Trivers 1971).

Cooperating in groups was likely favored by evolution for a variety of reasons including having greater access to resources, as well as protection from and ability to fight against threats (Greene 2013; Tooby and Cosmides 2010). From an evolutionary point of view, kin selection paired with processes related to and as a result of reciprocal altruism explains a large amount of ingroup activity, including social exchange, helping behavior,

and parental care. These features of human social life likely form a large part of the human moral architecture (Curry 2016). The notion that ingroup activity forms a large part of human life is also supported by the fact that humans evolved in small-scale conditions in which they interacted with a relatively small number of individuals many of whom were kin and close acquaintances (Dunbar 1992).

While reciprocal altruism is one biological mechanism that explains altruism and cooperative behaviors with people besides our kin, ingroup favoritism and cooperation between kin often limits the scope of altruism and cooperation. Greene (2013) argues that while morality evolved for cooperation, it primarily favors cooperation *within* groups and not necessarily between groups. In other words, people's morality is geared towards favoring themselves first along with loved ones and personal acquaintances. However, it becomes a stretch to expand that sphere of morality to strangers. Greene (2013) views this conundrum of human social life as analogous to the Tragedy of the Commons, where the pursuit of individual self-interest leads to a result that is collectively worse off for everyone involved. He refers to this dilemma as the Tragedy of Commonsense Morality.

The tendency for people to favor the groups to which they belong and act with antipathy and hostility towards the groups to which they do not belong is part of a larger psychological phenomenon than morality known as tribalism (Clark et al. 2019). Tribal phenomena include a number of cognitive and behavioral manifestations of ingroup–outgroup dynamics, which can be seen at every level of human social life.

Some of the tribal behaviors and cognitions people exhibit include ingroup favoritism (Balliet et al. 2014; Clark et al. 2019), discrimination and hostility towards outgroups (Balliet et al. 2014; Tajfel and Turner 1979), biased moral reasoning (Ditto et al. 2009; Clark et al. 2019), evaluating identical information more favorably when it supports one's political beliefs (Ditto et al. 2018), avoiding and being more critical of information that goes against one's beliefs (Kahan et al. 2017), ideologically motivated reasoning (Kahan 2013), and political polarization (Stroud 2010).

The Origins of Human Morality

Morality may be a feature that is unique to humans. Indeed, morality is fundamental to human life. Evidence shows that infants are capable of distinguishing good and bad behaviors within the first year of life. Six- and ten-month-old babies not only recognize helpful and hurtful actions in an experimental environment, but also have preferences for a helpful over a hurtful agent (Hamlin et al. 2007). By the second year of life, babies begin to develop the capacity to distinguish fairness (Sloane et al. 2012), prosocial sharing (Brownell et al. 2013), and empathy (Gubler and Bischof 1991).

Sharing behavior in primates exhibits rules and regularities similar to the moral concern in human behavior, to preserve a hierarchy, protect resources, and prevent cheating (Flack and De Waal 2000). After a fight occurs between two chimpanzees, they will sometimes show what looks like forgiveness and reconciliation, for example, “kissing” to reconcile and embracing for consolation (Greene 2013). However, significant differences in moral-like behavior in chimpanzees, such as the absence of anything like a moral conscience that involves internalizing group norms, and the absence of remorse for violent behavior, have prompted Boehm (2017) to make the analogy of chimpanzees to human psychopaths.

Coalitional Psychology

Similar patterns of human and chimpanzee intergroup conflict have led many researchers to study evolutionary parallels between these two species (Wrangham and Glowacki 2012). Intraspecific violence in chimpanzees and humans is often coalitional, where members of the species band together and express intergroup hostility (Wrangham and Glowacki 2012). The capacity to coalesce into coalitions is a necessary condition for intergroup conflict and warlike behavior (Tooby and Cosmides 2010).

Coalitional ties can result in negative judgments towards outsiders, such as representing healthy outgroup members as being infectious

(Petersen 2017). Affiliation helps to explain why people of different group-orientations are differently affected by the same information. For example, differences in moral values between political affiliations affect how disturbed one is to moral violations like kicking a dog, burning a country's flag, and slapping one's father (Graham et al. 2009).

The fact that individuals have a need to belong to a group (Baumeister and Leary 1995) and affiliations are often tied to location (Balish et al. 2013) provides a plausible path for moral tribes to be constituted in sports. Team sports may provide individuals a representation of an adapted form of conflict (Sell et al. 2017). Teams seem to have a form of morality that is enhanced by different regional divides (Balish et al. 2013). The zero-sum nature of sports (i.e., winners imply losers) gives individuals the thrills of winning, but also the pains associated with defeat. Stressful matches being played have been shown to negatively affect one's health, increasing risk of strokes and cardiovascular problems (Wilbert-Lampen et al. 2008). The fact that people are physiologically connected to the outcomes of their team shows how salient an identification with a sports team can be for an individual.

Moral and Political Tribes

Curry (2016) posited a multifaceted nature of morality that corresponds to its many-solutions based nature. These multiple parts of morality evolved as game-theoretic solutions to distinct evolutionary problems of cooperation. The central problems of cooperation outlined by Curry (2016) are as follows: (1) the allocation of resources to kin; (2) coordination to mutual advantage; (3) exchange; and (4) conflict resolution. Curry et al. (2018) describe how humans have culturally and biologically evolved solutions to these moral problems.

For example, the problem of allocating resources to kin is largely solved by kin selection, which explains many instances of altruism and favoring behavior for kin (Hamilton 1964). The problem of coordinating to mutual advantage occurs in a variety of contexts that involve two

or more agents with insufficient knowledge coordinating their behaviors for mutual benefit. Solutions include a host of behaviors that involve signaling, public communicative calls, focal points, among other such behaviors (Curry et al. 2018). In support of his morality-as-cooperation theory, Curry et al. (2018) found that among 60 societies seven cooperative behaviors that encompassed the cooperative domains of the theory were found to be uniformly positive.

Additionally, when it comes to politics, evidence indicates that conservatives and liberals emphasize different moral values, which constitute separate moral tribes (Graham et al. 2009). For example, liberals tend to emphasize harm and fairness concerns more than conservatives (Graham et al. 2009). Harm concerns include actions that make use of violent force against others which results in pain and suffering, while fairness concerns include actions that result in the unequal allocation and access to resources for individuals falls (Haidt and Graham 2007). On the other hand, morality concerns for conservatives are more equally distributed across the five foundations. Concern for the groups to which one belongs, tradition and authority, sacred values, and purity are more salient values for conservatives compared to liberals (Graham et al. 2009).

In addition to fundamental differences in moral values, evidence indicates that conservatives and liberals are equally politically biased and thus susceptible to ideologically skewed beliefs and tribalistic tendencies (Ditto et al. 2018). Together the findings on moral differences and political biases between liberals and conservatives help to explain why they are so often at cross-purposes; they are often not even speaking the same language (Haidt and Graham 2007).

Conclusion

For many decades, research from a variety of disciplines has converged on the finding that humans often engage in ingroup favoritism and express outgroup hostility, which constitutes the essence of tribalism. When this tribal tendency becomes moral, as it often does in intergroup conflict, politics, and when faced with cooperative problems,

people are more likely to be tribal and the tribal behaviors are more likely to be severe. This is because problems that are moral are ones that humans value deeply and strongly identify with and thus are willing to sacrifice for. The last few decades have presented new and unprecedented challenges for the expression of our evolved tribal tendencies with the rise of the internet and social media. Only with a better understanding of our nature, can we better know how to meet these new challenges and successfully solve them.

Definition

Human morality constitutes the by-product of evolution as it emerges from a continuum of shared behavioral characteristics between human and nonhuman species. Natural selection has rendered moral behavior to seemingly constitute a highly developed trait expressed by human primates.

Introduction

Contrary to the belief that wants morality to encompass a trait unique to humans, it is argued that other animal species may possess moral behaviors including community concern, reciprocity, and empathy. Although it is not supported that a fully developed moral system is present in other animals, it is indicated that human morality is embedded in phylogenetic relationships with ancestral animal species. Evolutionary scientists depict the phenomenon of homology by rendering the presence of shared behaviors as the result of a common ancestor between humans and other animal species. They also support that two distantly related species can share a behavior while they inhabit similar environmental niches as it results from convergence due to shared environmental constraints. Intriguingly, through examining behavioral patterns of other species might explain mechanisms of human behavior and depict that a multitude of phenomena concerning morality are the result of continual evolution.

The Empirical and Normative Senses of Morality

Morality from a scientific perspective refers to a set of empirical phenomena, such as the observed capacity of human beings to make normative judgments and the tendency to have certain sentiments including sympathy, guilt, or blame as well as intuitions about fairness and violence. Scientists speak of the Evolution of Morality in empirical sense while utilizing tools as comparative genomics and primate studies to analyze the

subject of interest. While morality in the normative sense is not an empirical phenomenon to be explained, there are vital points that require attention regarding evolutionary theory and principles (Rosenberg 2006).

The Normative Sense of Morality questions one's evolutionary background for moral guidance; through the normative approach, scientists might attempt to gain insight into the content of morality as claimed by proponents of prescriptive evolutionary ethics. Evolutionary theory can potentially explain metaethics and allow to resolve inquiries about the existence and nature of morality (Boniolo and de Anna 2006). Once topics of interest are selected, scientists begin to consider scientific explanatory projects concerning morality in the empirical sense.

Moral Behaviors in Nonhuman Species

Moral emotions have been identified as the principle mechanisms that uphold the rules of behavior underlying social norms and conventions. They constitute vital components in interactions as they normalize the behaviors of group members and foster the tendency to be in line with the norms (Haidt 2003). Equity and equality are the two primary elements that synthesize justice. Adam Smith refers to justice as "the main pillar that upholds the whole edifice of human society." This perspective lies within the rationale that wants animal species to react in the face of unfair treatment (Tinklepaugh 1928). This notion argues that based on instincts of moral behavior, primates tend to respond negatively when others are treated less well (Fletcher 2008), fact that contributes to the maintenance of harmonious coexistence among group members (Brosnan 2006).

Evolution of Justice

The sense of justice is seen in nonhuman primates as they are likely to respond negatively to earning less preferred rewards than a social partner (Frank 1988). In respect to natural selection, researchers argue that it might have been a critical environmental factor that led to selection for the behavior

(Darwin 1964). It is important to underline that evolution of shared behaviors does not indicate identical approaches from species as well as it does not eliminate the novelty of behaviors that are unique to specific primates, but not others, due to their complex nature (Flack 2000). Nonetheless, inequity can be explained as the by-product of another behavior that led individuals to selectively focus on conspecifics, such as social learning, which is present in many species and can be beneficial (Tangney et al., 2007). On the other end of the spectrum, inequity superficially might not be perceived as rewarding from species due to unjust circumstances; however, reacting negatively to unfair treatment can cease harmful interactions with opponents and encourage them to seek out equitable partners (Brosnan 2006). There is also evidence that human and nonhuman species actively take steps toward rectifying inequity when the moral sense of justice is violated and they receive less than they deserve (Brosnan, 2008). In this stage, primates react by punishing others who do not play fairly (Fehr and Gächter 2002). It can be argued that reaction to disadvantageous inequity is more salient as there is immediate benefit to the partner. On the other hand, advantageous inequity leads individuals to abandon their own good and act against their short-term self-interest in order to give up rewards to benefit others. The definition in itself might seemingly appear disastrous for the individual; however, it derives long-term benefits for the community and the conservation of healthy social norms.

Studies on Moral Behavior in Primates

Naturalistic studies have shown that long-term behavior of the partner is more important than the outcome of the individual. In an experimental cooperation task, subjects were more likely to cooperate if they and their partner evenly shared the rewards. In one study, monkeys had to work together to pull a heavy tray of food. The foods differed every time, and the monkeys had to decide whether they were willing to work for the food reward they were offered. Pairs in which the partners shared the good food about half of the

time were successful in the cooperative task, while pairs in which one partner eliminated the other rarely obtained cooperation (Burnham and Kurzban, 2005). Aside from the fact that non-sharing dominants received higher value rewards than their partners, their success rate was lower; thus, they tended to receive fewer rewards. The subjects seemed to expect that working together on a task leads to equity if reward outcome and dominant partners who failed to do this received a form of punishment (Brosnan et al. 2006). The findings indicate that a critical factor in a cooperative task is the partner's behavior to be equitable, rather than the actual value of reward. In experiments where participants are humans (Boesch 2007), responses to inequity differ depending on the source (Silk et al. 2005). Humans change their responses if there is a reason for inequity (Hagan and Hammerstein, 2006). Individuals offer less, and partners accept inequity more readily if the subject is perceived to have earned the right to it. Interestingly, humans tend to respond more negatively to inequity that is caused by another human directly than to inequity that is the result of chance.

Darwinism and Moral Emotions

Charles Darwin proposed that the basis of morality is innate and that humans and animals share an evolutionary background. He mentions in his book *The Descent of Man and Selection in Relation to Sex* that nonhuman primates possess social instincts, such as parental affection, and they are consequently characterized by a sense of conscience that would be otherwise intellectual power if it was well developed as it is in humans. It is argued that other animals experience some level of sympathy for others in their environment that also includes a strong need for familial interactions (Darwin 1964).

Darwin does not disregard the importance of advanced intellectual ability for meaningful judgment, but he underlines that well-marked social instincts are present in animals indicating moral constraints and conscience in species other than humans (Darwin, 1981). He supports that this

notion functions as an evidence for evolutionary continuity between humans and other animals as he relied on comparative data regarding facial expressions across human cultures and other species. He addressed the reasons why universal behaviors are expressed in the form that they do (Darwin 1998).

Adam Smith and Morality

Smith appears to support Darwinian theory. In his book *The Theory of Moral Sentiments* discusses that both positive and negative passions are seen in animals and that they share many traits that are considered human. To support his views, Smith mentions that all animals, including children and dogs, are likely to become angry at inanimate objects that hurt. He highlights that human instincts were in place to promote survival and reproduction. He further believed that instincts were initially experienced as emotion, rather than rational thought, and were often lied outside conscious awareness (Smith 1817). The idea of evolutionary continuity of behavior and the recognition of moral emotions has its roots embedded in the ancient past (Ekman, 1998).

M

Conclusion

A better understanding of the evolution of moral behaviors can be achieved through examining outcome behaviors that allow for insight in the past. According to the notion of natural selection, salient behaviors were practiced more than others, rendering certain moral tendencies as vital for survival. Values of justice and equity appear to be among some of the most crucial components to maintain social norms and order intact in communities of human and nonhuman animals. Undoubtedly, intellectual ability and moral judgment of humans are not comparable with those of other species; nevertheless, the presence of social instincts functions as an evidence of moral conscience in other species. With respect to moral behaviors and emotions, through approaching the precursors, such as the inequity response, scientists may gain a better insight into the outcomes

of evolution of moral behavior. Since clear continuity has been determined between the species, it can function as the foundation of future research on evolutionary approaches to human morality.

Morality Is Cooperation

Definition

Morality evolved as a mechanism to enhance cooperative behaviors and discourage cheating.

Introduction

Modern humans live in highly collaborative social groups. Although it has been theorized that human sociality only begins to develop as infants internalize symbols of the cultural world around them (Vygotsky 1978), recent research instead suggests that sociality may begin to form before infants are even able to take part in this cultural environment. Research by Michael Tomasello and Amrisha Vaish (2013) has shown that very young infants can already perform cognitive functions that other apes cannot, including cooperative communication. That infants who have yet to embrace any culture or language have performed with higher levels of cognition than adult apes supports theories that human sociality is not embedded entirely in the cultural world, but instead has its roots in the unique human evolutionary history. Additionally, as humans evolved into the ultra-cooperative beings seen today, the competition to be chosen as a partner may have contributed to an environment that became inundated by moral rules and expectations. Ultimately, there is much evidence to suggest that morality exists in humans as a mechanism to heighten cooperative actions and control cheating within groups.

The Interdependence Hypothesis

It is likely that there was a period of progression between the relatively low levels of cooperation of our distant evolutionary ancestors to the high levels that exist in today's human societies. Tomasello et al. (2012) present a theory to describe how humans came to be highly moral and cooperative individuals. They hypothesize that during human evolutionary history, humans began collaborating with others in order to survive and reproduce. Once individuals became interdependent, they also became altruistic, as their success was now contingent upon the success of their partner. This is called the *Interdependence Hypothesis*, and it involves two crucial steps. In the first step, there was a change in the ecology that required humans to search for their food collaboratively. This forced individuals to (a) make the decision to forage together even

when it meant giving up the smaller food they already had, (b) solve the problem of dividing the food after the collaboration was over, and (c) control any potential cheating from individuals wanting the food without participating in the search. Individuals had to communicate their goals during their mutualistic collaboration, which enabled them to create new, joint goals. The joint intentionality present between collaborators forced each member to have an interest in the welfare and success of their partner, as their partner's success was now directly linked to their own. Tomasello and Vaish (2013) further argue that it was this interdependence that originally encouraged helping behaviors. Moreover, the competitive partner choice market would have stimulated cooperation and discouraged cheating, as reputation was undoubtedly an important aspect for being chosen as a partner.

The second step of the Interdependence Hypothesis occurred once group populations grew even larger and they began to compete with other groups (Tomasello et al. 2012). These pressures presented new problems for humans that required a much more dynamic social climate. The increasing group size led to difficulties learning about an individual's reputation, which then led to a decrease in many people's motivation to cooperate. This degradation of cooperation encouraged new group-wide goals and social norms to once again boost collaboration, which in turn created highly enforced mutual expectations for behavior that remained consistent throughout a group. Everyone within the group now had their own role and again depended on other members for their survival.

Morality Improves Cooperation

According to Tomasello and Vaish (2013), children will become moral beings once they can effectively collaborate with other individuals and fully join in the social norms and practices of their culture. Not only do individuals follow the norms of their culture; they also enforce them on others – and themselves – if rules happen to be broken. This leads to a collective morality within the group that individuals will work in accordance

with. In order for a behavior to be considered moral, it requires an individual to either suppress their own well-being for the sake of someone else's or adopt another person's self-interest for their own as well.

According to Baumard et al. (2013), morality is an outcome of the cooperative actions within groups and exists to fairly allocate the benefits of cooperation. They propose a two-step hypothesis to suggest how it has evolved. In step one of the evolution of morality, partner choice would always favor those who were fair cooperators during collaborative activities, even if their motivation for cooperating was selfish. Second, competition among the ultra-cooperative individuals to be chosen as a partner created a further requirement: an individual motivation for fairness. This social selection for fairness contributed to the expectation of highly moral human behavior seen today. They suggest moral behavior exists to benefit one's reputation as a good cooperator, as this can only be done by an individual with a genuine moral sense. The researchers argue morality was adaptive when competition for cooperative partners was extreme, and the most effective way to be chosen was to be fair and equitable with the profits of cooperation.

Conclusion

The studies discussed here have suggested that morality evolved alongside cooperation to encourage cooperators and discourage cheaters. Many other researchers have also suggested the root of morality lies in the evolution of cooperation, with, for example, Joshua Greene (2015) arguing that the function of morality is to support cooperation. Similarly, Tage Shakti Rai and Alan Page Fiske (2011) describe morality by its ability to create and maintain long-term cooperative relationships. Frans de Waal (2006) has emphasized that just because natural selection is a ruthless progression through time does not mean it cannot also proliferate pleasant behaviors like fairness, cooperation, and morality. Natural selection

simply supports organisms that successfully reproduce and ignores the mechanisms that make them successful. Additionally, although the process of natural selection did not classify what our particular morals and norms would be, it did set the groundwork for human kindness and allowed morality to flourish.

Religion and development of civilization

Definition

Gods and their moralizing values, especially the powers regarding punishment, are related with how civilizations rose and developed into large societies.

The emergence of human civilization is related to the power of large-scale cooperation. Although cooperative behavior is seen in most mammals, large-scale cooperation extends beyond genetically related relatives. This type of cooperation, sometimes called ultrasociality, can be seen even in anonymous and one-time interactions but, without the reputational concern of any kind of large-scale cooperation, cannot be explained by standard evolutionary mechanisms. One of the hypotheses to solve this problem is the supernatural punishment hypothesis (Johnson and Krüger 2004). According to this hypothesis, the human surveillance mechanism does not observe and monitor every situation. However, the possibility of punishment by a supernatural agent eliminates the limitations of punishment for a person who violates moral rules. In other words, the mechanism of fear of supernatural punishment as an evolutionarily stable strategy explains why religions, and especially of religions with a moralizing high gods, spread (Johnson 2016). It is therefore thought that religious belief and

especially the belief in fear of supernatural punishment is an evolutionary adaptation to eliminate the problem of cooperation between large groups (Johnson and Krüger 2004; Johnson 2016). In this perspective, the existence of punishment by an omniscient and omnipotent supernatural agent eliminates the possibility of being not able to observe a moral violator among the communities of human beings with certainty in punishing a person who will make a moral violation. It is thought that the emergence of the idea of supernatural punishment is what underlies the ultrasociality commonly seen in human societies (Purzycki et al. 2016; see also Norenzayan 2013).

In other words, it is thought that there is a relationship between the emergence of moralizing religions and cooperation. For example, the emergence of big moral religions is believed to force people to move together around the temple and thus lead to the agricultural revolution (Norenzayan 2013). The fact that the temples in Göbekli Tepe are dated to a time before the agricultural revolution supports this view (Schmidt 2000).

In addition, different findings using different methods seem to support the supernatural punishment hypothesis. For example, people who believe that God has a punitive character do less cheating behavior on a subsequent task, while participants who believe in God's forgiving aspects show significantly more cheating behavior in the task (Shariff and Norenzayan 2011). In a cross-cultural analysis of national crime rates, Shariff and Rhemtulla (2012) found that there is a negative correlation between the degree of believing in hell and the national crime rates, but there is a positive correlation with the degree of belief in heaven. In a study of 186 different cultures, Johnson (2009) found a positive relationship between the belief in a punitive god and cooperation. Moreover, in a study conducted in eight different cultures, it was observed that a factor that increased the level of helping toward distant coreligionists is the belief that God has a punitive character (Purzycki et al. 2016). Yilmaz and Bahçekapili (2016) also experimentally

showed that activating the punitive aspects of religion caused a significant increase in prosocial intentions. More interestingly, in a way similar to the punitive effect of religion, activating the punitive aspects of secular institutions has similarly led to an increase in prosocial intentions in the same study. This shows that, in addition to religious authorities, punitive secular authorities have similar power in cooperation in contemporary civilization. Likewise, in the study of Shariff and Norenzayan (2007), activating religious or secular institutions had a very similar effect on prosocial behavior.

As a result, these findings support the argument that societies that believe in punitive and omnipotent supernatural powers are more cooperative, and less selfish, which in turn expand and create our large-scale civilization (see Norenzayan 2013).

Morbid Jealousy

Sujita Kumar Kar and Nitika Singh
Department of Psychiatry, King George's Medical University, Lucknow, UP, India

Synonyms

[Pathological jealousy](#)

Definition

It is an intense form of jealousy, mostly involving the intimate interpersonal relationship, and it produces significant distress and impairment.

Introduction

Jealousy is a complex human emotion. The Cambridge dictionary defines “jealousy” as “a feeling of unhappiness and anger because someone has something or someone that you want” (Dictionary 2015). Jealousy is often described as a negative emotional state. Jealousy as an emotion has a close link with anger and sadness

(unhappiness). Jealousy often results in unhappiness or anger. Jealous feelings are often discussed in the context of ownership (power, possession), performance, sexual activity, and love (Bhugra 1993; Zandbergen and Brown 2015). Jealousy is also strongly linked to the emotion “love.” Love gets colored with jealousy, when it demands the “exclusive, unconditional, continued and total possession of the romantic partner” (Maggini et al. 2006).

In the history of literature, the word “jealousy” was frequently used and denoted to a negative feeling state. Interestingly, it had caught the attention of poets and artists to be depicted in popular literary creations (Shepherd 1961). In literature, the words “jealousy” and “envy” are interchangeably used. A finer difference exists between these two words. Envy refers to the feeling that an individual experiences when the individual wants something that he/she does not possess. Jealousy refers to the feeling state that an individual experiences in response to a threat of impending loss of something that the individual possesses (Bhugra 1993).

Sometimes, jealous feelings become very intense, which lead to significant interpersonal impairment and produces clinically obvious distress. It is often referred as “pathological jealousy,” “delusional jealousy,” “erotic jealousy,” or “morbid jealousy” (Miller et al. 2010). Morbid jealousy is often discussed in the context of spousal relationship. Morbid jealousy often results in irrational thoughts and behavior, which are extreme and unacceptable (Kingham and Gordon 2004). It is important to differentiate the feeling of jealousy experienced by normal people from the individuals who experience morbid jealousy. People often experience jealousy after a firm or robust evidence of unfaithfulness, and often they have the readiness to accept alternative thoughts; however, those with morbid jealousy often harbor their belief without robust evidence and offer strong resistance to accept alternative possibilities (Kingham and Gordon 2004). Certain predisposing factors have been identified for morbid jealousy in spousal relationships, which are attractiveness of the partner, partner working at a distant place from

home, and partner having interaction with opposite gender (Singh et al. 2017). Morbid jealousy is broadly classified into two subtypes (Mullen et al. 1990):

1. *Symptomatic jealousy*: Here, jealousy evolves in the background of a psychiatric disorder. As the underlying psychiatric disorder progresses, jealousy evolves concurrently. For example, delusion of infidelity in paranoid schizophrenia or persistent delusional disorder.
2. *Reactive jealousy*: Here, jealousy develops as a reaction to underlying mental state (low self-esteem), psychosocial circumstances (e.g., relational difficulties with partner), or mental illness (e.g., depression). Reactive jealousy is considered as an independent psychopathology, different from the comorbid psychiatric illness or condition that provoked its development.

The Othello Syndrome

The Othello syndrome refers to “delusional jealousy” (Leong et al. 1994). Patients with Othello syndrome often display outbursts of anger and hostility. Their anger may result in verbal threats and physical fights to homicidal behavior in extreme conditions (Leong et al. 1994). Othello syndrome has been reported in the context of schizophrenia and related psychotic disorders, organic mental disorders, personality disorder, substance use disorder, and even some neurotic conditions (Alarcon 1980). The prevalence is almost equal in both genders, but higher prevalence is reported among old people (Seeman 2016).

The etiopathogenesis of Othello syndrome can be linked to certain biological (e.g., neurological conditions like dementia, organic brain syndrome, drug induced), psychological (e.g., paranoid personality, borderline personality, low self-esteem), as well as social (e.g., excessive dependency on the partner, rejection, or altercation with the partner) factors (Seeman 2016).

The core symptom of Othello syndrome is “delusion of jealousy” or “delusion of infidelity”

(Alarcon 1980; Cipriani et al. 2012). When it is developing in the context of dementia, cognitive deficits, hallucinations, and other delusions may accompany (Cipriani et al. 2012). Violent behavior in dementia can be secondary to the delusion of jealousy. Similarly, patients with Parkinson's disease on antiparkinsonian treatment may report about symptoms of Othello syndrome (frequently paranoid and sexual delusions), which often improves with reduction of dopamine agonist agents (Kataoka and Sugie 2018). In the background of obsessive-compulsive disorder, pathological jealousy related to the fidelity of spouse or partner has an obsessional quality (recurrent, repetitive, intrusive, unpleasurable, and irrational). In the context of schizophrenia and related psychotic disorders, morbid jealousy-related spousal relationship is often firmly held and cannot be convinced by contrary evidences. It is often accompanied with keeping a close watch on the partner and partners belongings (Singh et al. 2017).

As the patient may pose threat to self, partner as well as to the rival during the course of the disorder, there is a urgent need of treatment for prevention of untoward consequences (Seeman 2016). Treatment for Othello syndrome can be done pharmacologically (by using antipsychotic medications) or through psychological interventions (e.g., cognitive therapy, couple therapy) (Seeman 2016).

Morbid Jealousy and Alcoholism

Morbid jealousy is often discussed in the context of alcoholism. The prevalence of morbid jealousy among individuals with alcohol use disorder is found to be as common as 34% (Michael et al. 1995). Morbid jealousy in alcoholics can be reported during the state of intoxication, or it can be seen as a comorbid delusion (Michael et al. 1995). Morbid jealousy related to sexual relationships and intimacy is more commonly seen in individuals with severe form of alcohol use disorder (Shrestha et al. 1985). Violence particularly involving the domestic setting and spouse is commonly associated with alcoholism. Morbid

jealousy involving the sexual relationship can be one of the major contributors to alcohol-related violence (Coid 1982).

Morbid Jealousy: Social and Evolutionary Significances

Jealousy has many evolutionary advantages. In the process evolution, there occurs competition in the environment. Those who are able to compete better survive, and those who fail to compete become extinct. Jealousy is one of the determinants of competition. Jealousy related to achievement, possession, power, and procreation (love and sex) acts as a triggering factor for competition. Jealousy as a "mate-guarding" phenomenon is also seen in other primates. Jealousy is capable of producing social pain in a partner, when the other partner is found to be engaged with a new partner or stranger as evident from the study on monkeys (Maninger et al. 2017).

As per the Darwinian hypothesis, jealousy has fitness advantages for both man and woman from evolutionary point of view. Jealousy may be a determining factor for mating (Harris 2004). Jealousy carries different evolutionary significance for males and females. Jealousy in males is mostly related to the risk of sexual contact of their partner with other males (rivals), which reduces their paternity probability, whereas in females, jealousy is not due to reduced maternity probability as females retain their maternity probability, irrespective of their partner contact. The jealousy in females is due to the risk/fear of digression of their committed sexual partner to other female partners for sexual contact (Buss et al. 1992).

Jealousy in sexual relationships may be advantageous as it facilitates the propagation of own genes (Singh et al. 2017). Jealousy may also stabilize the romantic relationship; however morbid jealousy destabilizes the romantic relationship (Sun et al. 2016).

Morbid jealousy may have evolutionary significance. It has been seen that greater percentage of males with morbid jealousy often doubt the sexual fidelity of their partner, whereas greater

percentage of females with morbid jealousy doubt about the emotional fidelity of their partner (Easton et al. 2007). Males and females with morbid jealousy are often preoccupied with the status and attractiveness of their rivals, respectively (Easton et al. 2007).

Evidence supports that morbid jealousy or pathological jealousy falls in the same spectrum of pathological love; however, there are subtle differences in their love style and attachment style. Avoidant attachment is characteristic feature of morbid jealousy, whereas secure attachment is characteristic of pathological love (Stravogiannis et al. 2018).

When compared with healthy individuals, individuals with morbid jealousy are often high in impulsivity, trait anxiety, novelty seeking, and harm avoidance. They have low cooperativeness and self-directedness and poor social adjustment (Costa et al. 2015).

Morbid Jealousy: Neurobiological Implications

Morbid jealousy is seen commonly in the context of organic mental disorders. Evidence suggests that in approximately 30% cases, a neurobiological attribute can be traced for the Othello syndrome (Cipriani et al. 2012). Frontal lobe dysfunction is possibly implicated for morbid jealousy. Dopamine excess has been implicated in the development of morbid jealousy of Othello syndrome. Patients with Parkinson's disease with Othello syndrome reported reduction to resolution of their delusions of jealousy after decreasing the dose of dopaminergic agonists (Kataoka and Sugie 2018). Evidence supports that morbid jealousy (delusion of jealousy) develops after cerebrovascular accidents (stroke), head injury, and brain tumors (meningioma) (Kuruppuarachchi and Seneviratne 2011). Neuroimaging studies found that when people are exposed to scenarios of romantic jealousy, there occurs activation of the basal ganglia. Similarly, the intensity of morbid jealousy related to romantic relationship is correlated with the activation of ventromedial prefrontal

cortex (VMPFC) (Sun et al. 2016). Studies among monkeys revealed that feeling of jealousy produces alteration of glucose metabolism in specific brain areas. During jealous state, there occurred increased uptake of fluorodeoxyglucose (FDG) in the left anterior and posterior cingulate cortex, whereas FDG uptake is lowered in the right medial amygdala (Maninger et al. 2017).

Conclusion

Jealousy is an essential emotion and does have a role in the survival of an individual as well as a race. Morbid jealousy should be always differentiated from non-pathological jealousy. Morbid jealousy can be a core feature of various psychiatric disorders and is treatable. One needs to be familiar with the antecedents and consequences of morbid jealousy for its holistic management.

Definition

Homicides that occur are overwhelmingly committed by males.

Introduction

Across cultures, homicides are overwhelmingly perpetrated by males. The UN Office on Drugs and Crime (2013) reports that 80–97% of homicide perpetrators are men. Men kill other unrelated men in cases of conflict over social status, face, pride, and reputation, as well as conflict over material resources. Men also often kill women as the result of sexual jealousy. It is very rare for women to kill other individuals. This, however, does not mean that women's level of competition with other individuals is trivial, rather women often use indirect tactics of competition, such as verbal assault or manipulation of other individuals.

Men as the Perpetrators of Homicide

From an evolutionary perspective, men are more likely to be the perpetrators of homicide because there are greater incentives for them to do so. Men's reproductive success is limited by their ability to gain access to mating opportunities. As a result, sexual selection theory predicts that, to avoid the possibility of reproductive oblivion, men must compete with other men for access to women (Trivers 1972). Competition over direct

access to women, as well as competition over resources that will indirectly increase men's mating prospects, may turn fatal.

The homicide rate for male perpetrators increases sharply during the late-teens, peaks during the early 20s, and then rapidly decreases afterwards. A similar peak is present for women, but the magnitude is much lower than that of men. Moreover, across life span, the homicide rate for men exceeds that for women (Daly and Wilson 1988). The evolutionary explanation for this age-homicide curve is that this peak age of homicide corresponds with the life-stage where mating goals loom large, and therefore, competitiveness and the reputation for a readiness to fight is most crucial. Men of this age-category are much more willing to engage in a variety of risky behaviors, such as dangerous driving, sports participation, and excessive drinking, than men in other age-categories. This willingness to accept a high degree of risk likely contributes to the tendency for conflicts between men to escalate quickly to violence and, sometimes, homicide.

Independent of the age effect, male homicide perpetrators tend to be unemployed, poor, and of low education as compared to the general population (Daly and Wilson 1988; Hiraiwa-Hasegawa 2004). These individuals are likely to have difficulty attracting mates using other means and may therefore resort to physical violence to deter competitors. Along similar lines, having a family appears to have an inhibitory effect on men's violence (Daly and Wilson 1988). Although this effect has not yet been demonstrated clearly, it is consistent with the evolutionary perspective – that men who have access to mating opportunities already have less incentive to engage in risky, violent behavior in order to gain additional opportunities.

When men kill women, the most frequent motive is sexual jealousy. Men facing a situation in which their romantic partner leaves them, even when there is no new partner to compete with, may result in a violent, and even deadly, response. Sexual jealousy like this is thought to be an adaptive psychological mechanism for mate-guarding and paternity assurance (Daly et al. 1982). Women usually do not kill their male partners in the same situation, because female-female competition for acquiring mates is weaker among

females than among males, and the costs of violence are greater in females than in males.

Women are generally unlikely to be the perpetrators of homicide, given their large investment in offspring. Indeed, women are essential to the survival of their offspring (Sear and Mace 2008). Thus, engaging in high-risk violent competition poses a serious threat to their reproductive success. Consequently, women adopt more subtle, indirect tactics such as gossip and social exclusion, thereby attacking the competitors without the danger of physical violence.

Conclusion

Across cultures, most perpetrators of homicide are men. Evolutionary psychology can explain this phenomenon from the theory of sexual selection. Men's reproductive success is limited by their ability to gain access to mating opportunities. As a result, men must compete with other men for access to women. Competition over direct access to women, as well as competition over resources that will indirectly increase men's mating prospects, may turn fatal. Men also more likely to kill women for the purpose of mate-guarding than women in the same situation. Women are unlikely to be the perpetrators of homicide, given their large investment in offspring. This does not mean that women do not compete each other, but women adopt more subtle, indirect tactics, thereby attacking the competitors without the danger of physical violence. The homicide rate for male perpetrators increases sharply during the late-teens, peaks during the early 20s, and then rapidly decreases afterwards. This is also explained by the sexual selection theory: that this peak age of homicide corresponds with the life-stage where mating goals loom large, and therefore, competitiveness and the reputation for a readiness to fight is most crucial.

Definitions

Homicide that occur overwhelmingly victimize men.

Introduction

Across cultures, when homicides are committed, they overwhelmingly victimize men. The UN Office on Drugs and Crime (2013) reports that

95% of homicide victims are men. Indeed, most homicides are both perpetrated by, and targeted at, men.

Men as the Victims of Homicide

Statics in modern, developed countries show that the homicide victims, as well as the perpetrators, are predominantly men. For instance, the US Department of Justice (2010) announces that murder victims in the United States in 2010 consists of 10,058 men, 2918 women, and 20 cases where the sex was unknown: almost 78% are men. The Office for National Statistics in the United Kingdom (2015) reveals that, in 2015, the homicide victim rate for men was 11.7 per million whereas it was 6.4 per million among women. The same pattern can be found in the WHO's mortality statistics (2016), showing a rate of male deaths by assault that exceeds those of females for nearly all countries reported. The US data is broken down by each age category and demonstrate that across all age categories, with the exception of infant under 1 year of age, males are more likely than females to be the victim of homicide.

An evolutionary explanation of this pattern of findings is linked to the tendency for males to be the primary perpetrator of homicides. Men are more likely to be the perpetrators of homicide because there are greater incentives for them to do so. Men's reproductive success is limited by their ability to gain access to mating opportunities. As a result, to avoid the possibility of reproductive oblivion, men must compete with other men for access to women (Trivers 1972). Competition over direct access to women, as well as competition over resources that will indirectly increase men's mating prospects, can turn fatal. This violence is directed against men, not women, because other men are the obstacle to men's attempts to gain mating opportunities. The violence is not typically directed against women, as they are the desired resource to whom men are competing.

On the other hand, men's attempts to prevent their mating partners from leaving the relationship, or suspected infidelity, may turn deadly. However, this type of homicide is relatively rare

in comparison to the proportions of homicides that are male on male.

Conclusion

Across cultures, when homicides are committed, they overwhelmingly victimize men. Statistics in modern, developed countries clearly demonstrate this pattern; the proportion of men in all the homicide victims usually amounts to more than two thirds. This pattern is linked to the tendency for males to be the primary perpetrator of homicides. Men's reproductive success is limited by their ability to gain access to mating opportunities. Competition over direct access to women, as well as competition over resources that will indirectly increase men's mating prospects, can turn fatal.

Mother Hypothesis

- Grandmother Hypothesis, The

Mother Tongue Hypothesis

Mark Pagel

School of Biological Sciences, University of Reading, Reading, UK

Synonyms

Proto-language; Proto-Sapiens; Proto-World

Definition

Either a person's native language or a hypothesis about the original human language.

Introduction

The phrase “mother tongue” is often used to indicate someone's native language, as in “what is your mother tongue?” But in linguistics and anthropology “mother tongue” is a hypothesis about the origins of human language. In this context “mother tongue” refers either to the original or first human language or to the most recent common ancestor of all extant or currently existing human languages.

Monogenesis of Language

Many scenarios for the origin of human language are possible (Fig. 1). Here “origin of language” can be understood to mean not just people starting to talk, but to the origins of the apparatus – the cognitive, neurological, and anatomical specializations – that make language possible and the genetic architecture that gives rise to them. Some theoreticians believe that this language faculty arose as a specific adaptation for language (Pinker and Jackendoff 2005), while others argue that it evolved for more general cognitive reasons and was only later co-opted specifically for language (Hauser et al. 2002; Christiansen and Chater 2008).

Figure 1a depicts a scenario known as “monogenesis” in which the capacity for language evolved only once, and all modern languages descend from a single original or protolanguage (e.g., Bickerton 1990). Spoken language itself might descend from earlier “gestural” forms of communication (Corballis 2003). Early on in the evolution of spoken language, many private “protolanguages” might have existed within family units (Fitch 2004), but the evolutionary advantages of language meant that it eventually became a public and shared “technology.”

In contrast to monogenesis, there might have been more than one origin of the capacity for language (Fig. 1b, c), and these separate capacities need not have evolved at the same time. In the case of more than one origin, all modern languages might descend from one of these founding events (Fig. 1b) or from more than one (Fig. 1c). Even if the modern languages descend from a single origin, they might trace their ancestry to a more recent common ancestor (Fig. 1b).

Proponents of “polygenesis” believe that the capacity for language arose early in the evolution of our species but that languages only emerged later and independently in various groups around the world (Coupé and Hombert 2005). “Polygenesis” should not be confused with the scenarios expressed in Fig. 1b and c which show separate origins of the capacity for language. Instead, here there is a single origin of the capacity for language, but specific social, environmental, or demographic factors are thought to have encouraged the formation and use of language and at different times in different places. This view of polygenesis has much in common with the argument that the language capacity emerged out of more general-purpose cognitive mechanisms.

Is it reasonable to think there was a single origin of the capacity for language (Fig. 1a)? All human groups that exist today have language, and they share a key gene known as *FOXP2* (Enard et al. 2002). This gene is thought to be involved in language and speech production and influences the fine motor control of facial muscles that are required for the production of speech (Enard et al. 2002). Genetic studies further show that all

Mother Tongue Hypothesis, Fig. 1 The diagrams show two scenarios for the origin and evolution of human languages. Panel (a) A single origin of language occurred in the remote past and all human languages throughout our species' 160,000–200,000 year history descended from that original or founding “mother tongue.” Branches that end in the present represent extant or currently existing human languages. Blue triangles represent collections of languages with a common ancestor. Branches that end

before the present represent extinct languages (such as Latin). Panel (b) The human language capacity arose more than once in separate populations, and not necessarily at the same time, but today all human languages trace their ancestry to just one of these origins. Panel (c) More than one origin of language and currently extant human languages trace their ancestry to these different origins. Other scenarios are possible

M

human groups have shared ancestry (e.g., Rosenberg et al. 2002).

In addition, all human languages rely on combining sounds to make words; many of those sounds are common across languages; different languages seem to structure the world semantically in similar ways (Youn et al. 2016); all human languages recognize the past, present, and future; and all human languages structure words into sentences with subjects (S), verbs (V), and objects (O) as in “I (S) kicked (V) the ball (O)” (Greenberg 1963). Finally, all humans are capable of learning and speaking each other's languages.

The similarities among languages and our apparently shared genetic influences on language in the form of *FOXP2* are consistent with the capacity for language having evolved just once, or if this capacity evolved more than once, all

modern languages trace their ancestry back to just one of these events. Genetic evidence points to all modern humans descending from a common ancestor that existed between 125,000–150,000 years ago (Poznick et al. 2013), suggesting that the capacity for language is at least that old.

On the other hand, our species is probably older than this common ancestor (analogous to the scenario for the mother tongue depicted in the right side of Fig. 1b), with fossil evidence suggesting modern humans evolved 160,000–200,000 years ago (Fleagle et al. 2008). Language transmits information using symbols, so it is reasonable to expect that any species that possessed language would show evidence of symbolic behavior. The appearance of symbolic behavior in the form of the use of red ochre pigments (Henshilwood et al. 2002; Henshilwood and Dubreuil 2009) might, then,

indicate that the capacity for language was present by 160,000–200,000 years ago.

Is Language Older than Our Species?

Could language be even older than our species? Might, for example, our genetic cousins the Neanderthals (*Homo sapiens neanderthalensis*) have had language? No one can know because this species went extinct by around 30,000–40,000 years ago. But if Neanderthals could speak, then the capacity for language might already have been present at the time of our common ancestor with them, now thought to be 550,000–765,000 years ago (Prüfer et al. 2014; Meyer et al. 2016).

The *FOXP2* gene in humans and Neanderthals is identical in its coding regions while differing at two key positions from the chimpanzee version of this same gene (Krause et al. 2007). The identity between humans and Neanderthals might suggest Neanderthals could speak. On the other hand, *FOXP2* is not “the language gene” as many genes will be involved in building a capacity for language, and very recent genetic evidence shows that the human and Neanderthal versions of *FOXP2* are expressed or used differently in our two brains (Maricic et al. 2013).

There is also scant evidence that Neanderthals had art or other symbolic behavior (Klein 1999); suggestions that they might have buried their dead or put flowers in the graves divide opinion and do not alone constitute evidence for symbolic thinking anyway. By comparison to Neanderthals, *Homo sapiens* who lived in Western Europe at the same time as Neanderthals had abundant and sophisticated art, they made musical instruments and had a far wider variety of tools and weapons.

We cannot be sure that Neanderthals lacked language, but it would be curious for a species that did have language to show so little evidence of putting it to use. By comparison, modern humans’ cultural and symbolic variety and the evidence of innovation and cooperation are just what we expect of a species that possessed a powerful medium for transmitting information.

A More Recent Origin of Language

Some authors suggest that the human language capacity might have arisen a mere 40,000–50,000 years ago in the modern human populations which had occupied Western Europe by that time (e.g., Klein 1999). The archeological record shows that this was a time of a great flowering of art, symbolism, and technology. Klein (1999) suggests this outpouring of culture indicates that an important genetic development occurred which gave rise to the cognitive abilities that language requires.

The suggestion of a late genetic change making language possible confronts several difficulties. One is that at least some modern human groups had probably left Africa by 120,000 years ago, making it all the way to modern-day China (Wu et al. 2015). Migrating this far would have required adapting to new environments, climates, and sources of food while outcompeting the species already there. Our ability to do this by 120,000 years ago may attest to an already fully developed system of transmitting culturally acquired knowledge, and the most likely medium of this transmission would have been language (Pagel and Mace 2004; Pagel 2012).

The suggestion of a recent emergence of language also struggles to explain the presence of similarly structured languages in human groups all over the world. Thus, for example, the San Bushmen of Southern Africa have the same linguistic capabilities as any other modern human group, but their lineage might have separated from most of the rest of humanity perhaps 100,000 years ago (Knight et al. 2003). For the language faculty to have evolved just 50,000 years ago would require that, somehow, the early Europeans of that time made their way back to Africa, and perhaps interbred with other groups, thereby giving them the capacity for language. There is no genetic or archeological evidence in support of this scenario.

A variant of Klein’s (1999) suggestion avoids the difficulties of proposing a late genetic change, by adopting the perspective of those who support polygenesis, as described above (e.g., Coupé and Hombert 2005). But even polygenesis runs into

difficulties when trying to explain humans' early symbolic behaviors (Henshilwood et al. 2002; Henshilwood and Dubreuil 2009) and apparent technological abilities. These capabilities, expressed early in our history as a species, evidently allowed us to transmit information culturally and adapt to new environments well enough to have occupied East Asia by 120,000 years ago (Wu et al. 2015).

What Was the Mother Tongue Like?

Writing is only around 5000 years old so archeology, beyond identifying symbolic behaviors, is not of much use in identifying traces of a mother tongue or suggesting what it might have been like.

Linguists, on the other hand, can look for words that are shared among enough human languages to suggest that they may be echoes of a shared mother tongue. Statistical investigations of the rate over long periods of time at which words get replaced by new unrelated words lend credibility to this pursuit (Pagel et al. 2007). In particular, some numeral words and pronouns (I, you, who, two, three, five) and the “wh” words or *who*, *what*, *where*, *why*, and *when* tend to evolve slowly enough that it might be possible to trace their ancestry back 10,000 years or more (Pagel et al. 2007).

Evidence that words can retain traces of their ancestry even beyond 10,000 years comes from studies of shared words among language families of Eurasia (Pagel et al. 2013) that probably shared a common ancestor around 15,000 years (Pagel et al. 2013). Two languages that have been evolving separately since a common ancestor 15,000 years before represent about 30,000 years of linguistic evolution over which some traces of similarity in a small number of words have been found (Pagel et al. 2013). Among these words are thou (you), I, we, who, and what.

Still, even 30,000 years of independent evolution doesn't take us back to a common ancestor that might have existed 100,000–200,000 years ago. Historical linguists adopting an approach called mass comparison attempt to identify shared combinations of sounds in widely geographically

separated languages, in hopes that these sounds might be echoes from this more distant past. The work is contentious and controversial among linguists (e.g., Campbell and Poser 2008) but one of its chief exponents, Merritt Ruhlen, working with another linguist, John Bengtson, has proposed 27 “global etymologies” (Bengtson and Ruhlen 1994).

The list of global etymologies includes words for *who*, *what*, *two*, *water*, and *finger* or *one*. For instance, Ruhlen points out that the sounds *tok*, *tik*, *dik*, or *tak* surface repeatedly in the world's languages as a word for the number one or toe or a digit. Other global etymologies include “?ak'wa” (water), “pal” for “two,” “half” for “portion,” “mi (n)” for “what,” and “ku(n)” for “who.” Might these be relics of a mother tongue? Intriguingly, Ruhlen's proposed global etymologies tend to be words that are frequently used in everyday speech, and it is these that tend to change the slowest (Pagel et al. 2007).

Conclusions

Genetics, the shared structure and the universal learnability of human languages, make it reasonable to believe that extant humans have a common language capacity that evolved just once and probably early in our history, perhaps 160,000–200,000 years ago. But the rate at which words evolve means that traces of our common language or “mother tongue” have proven difficult to find. Further clues for evidence linking the world's languages may yet come from studying vocabulary, but other sources such as patterns of tones and styles of prefixes and suffixes (Diamond 2011; Vajda 2010; Hruschka et al. 2015) may also prove useful.

Mother's Brain Size Decrease During Pregnancy

Alexis Goad and Shelia M. Kennison
Oklahoma State University, Stillwater, OK, USA

Synonyms

Baby brain; Momnesia; Pregnancy brain

Definition

During pregnancy, mothers' brains gradually decrease in size until parturition.

Introduction

During pregnancy, a mother's body goes through numerous physiological changes in order to become adequately prepared with the tasks of motherhood. One change that is not readily apparent to the mother or others is the shrinking of the overall volume of her brain. It has been found in both rats and humans that the size of a mother's brain decreases gradually throughout the gestation period, beginning at implantation of the fertilized egg (Chan et al. 2015; Oatridge et al. 2002). The amount of size decrease can vary between individuals, ranging from a 2% to 7% size decrease (Oatridge et al. 2002). Women with preeclampsia, a hypertension disorder acquired during pregnancy, can experience an even greater decrease in brain size (Oatridge et al. 2002). Although the total size of the brain decreases, there are actually increases in the size of the ventricles and the pituitary gland (Oatridge et al. 2002; Gonzalez et al. 1988). After parturition, the brain gradually returns to its pre-pregnancy size, taking up to 6 months (Brizendine 2006; Oatridge et al. 2002).

Causes of Size Decrease

While there is no consensus about the cause of brain shrinkage during pregnancy, there are a number of possibilities. Holdcroft et al. (2005) note that changes in brain size during pregnancy seem to be related to a change in cell metabolism. Six weeks after delivery, while the brain is returning to its original size, there is a significant increase in intracellular pH. While it is interesting to note that this change is only evident after the pregnancy has terminated, it may be a small part of the mechanism that causes the size change. In research with rats, Chan et al. (2015) postulated that a decrease in taurine leads to the change. Taurine helps prevent cell shrinkage in the brain, and its levels diminish during pregnancy.

Effects of Size Decrease

While the effects of a mother dealing with a shrinking brain are not life-threatening or large

enough to have significant effects on daily life, there are some reported changes that come with brain size fluctuations. When returning to its original size during the postpartum period, there is evidence showing that there are changes in the neuronal connections of certain areas of the brain (Chan et al. 2015; Kim et al. 2010). In rats, there is a reported increase in hippocampal bilateral connectivity during pregnancy (Chan et al. 2015). In humans, there is evidence of gray matter increase in certain areas of the prefrontal cortex, gyrus, parietal lobe, insula, and thalamus (Kim et al. 2010).

There are conflicting results in studies investigating changes in the cognitive abilities of pregnant women. Some find no diminished abilities, while others have found significant impairments in memory (Crawley et al. 2003; Buckwalter et al. 1999). Interestingly, in a study by Crawley et al. (2003), there were no significant differences in the abilities of verbal memory, focused attention, or divided attention between pregnant and non-pregnant women; however, pregnant women rated themselves as less skilled in those areas during their third trimester. This general view of cognitive impairment held by pregnant women is apparent in common media as well; the reported pregnancy-induced dimness is colloquially referred to as “baby brain” or “momnesia” (Knapton 2014).

Evolutionary Implications

Researchers have speculated about the possible evolutionary significance of a shrinking brain during pregnancy. According to the results of the study by Kim et al. (2010), the shrinking and then subsequent regrowing could help facilitate the refocus of neuronal circuitry in areas of the brain that facilitate motherhood and motherly behaviors. Because of metabolic changes, expectant mothers may limit their physical activity keeping them close to home and safe from predators and other dangers.

Conclusion

During pregnancy, there is a significant decrease in the size of the mother's brain up until parturition, after which the decrease is reversed (Oatridge et al. 2002). The effects of this phenomenon are not dramatic, but they are noticed by pregnant mothers (Crawley et al. 2003). While there is some intriguing evidence regarding causes and evolutionary implications of the size decrease, further studies are needed to help provide a more detailed understanding of how and why this aspect of pregnancy occurs.

Motherese

Tanya Broesch
Department of Psychology, Simon Fraser
University, Burnaby, BC, Canada

Synonyms

Baby talk (BT); Infant-directed speech (IDS)

Definition

Motherese refers to the ways humans (typically mothers or caregivers) alter their speech when addressing young infants or children compared to speech addressed to another adult.

Introduction

“Motherese,” also commonly referred to as infant-directed speech (IDS) or baby talk (BT), refers to the ways in which adults alter various aspects of their speech when addressing children and infants. This can be done in a variety of ways such as using simplified speech, repeating words, shortening sentences, as well as altering the acoustic properties of speech such as using higher pitch, increased pitch range, more pitch variability, and slowing down their speech rate.

The ways in which an individual changes their speech style depends on many factors, including the age and sex of the child as well as the culture they are living in and the relationship to the child (Cooper and Aslin 1994). IDS can be measured using structured or natural observations between an adult and a child (typically a caregiver and their infant) and comparing the speech to that between the adult and another adult in the same setting. Comparisons are then made between the speech samples to determine whether and how the adults modify their speech in the presence of the child. Furthermore, studies have shown that infants as young as 7 weeks prefer infant-directed speech to adult-directed speech.

There is evidence to suggest that this behavior is common across human societies and highly recognizable (Broesch and Bryant 2015; Bryant et al. 2012; Bryant and Barrett 2007; Fernald 1992), although there has been debate about the extent to which some societies address young children and alter their speech style. Research shows that vocal changes happen similarly across industrialized populations (Fernald 1992) as well as in small-scale, traditional societies (Broesch and Bryant 2015).

Several possible functions of IDS have been proposed. For example, IDS might aid in language learning specifically or learning in general (Thiessen et al. 2005; Csibra and Gergely 2009). There is evidence that IDS contains acoustic features that help children learn vowel categories of their language (Kuhl et al. 1997). IDS also likely helps communicate emotional information,

including effectively grabbing and maintaining the attention of infant listeners. In general, IDS also can facilitate an affective relationship between the adult and the child (Fernald 1989; Trainor et al. 2000). Infants demonstrate a preference for IDS over adult-directed speech (ADS) even when the IDS is in a language that is unfamiliar to the infant (Werker and McLeod 1989) suggesting that it is an excellent source of information for infants in early stages of perceptual and conceptual development.

Conclusion

Adults modify various aspects of their speech including acoustic properties, and speech style, often simplifying the nature of their speech and drawing attention to particular aspects of the language or the interactive context. There is evidence indicating that humans across the globe produce motherese. Infants also prefer IDS over ADS and learn more easily from it. It is thought that this behavior facilitates an affective relationship between a caregiver and his/her infant as well as enhances or enables the learning process.

Mothers and Maternal Grandmothers and Childhood Survival

Rebecca L. Burch
State University of New York at Oswego,
Oswego, NY, USA

Synonyms

Allomothering; Alloparenting

Definition

After mothers, maternal grandmothers have the largest effect on child survival.

Introduction

Arguably the greatest threat to reproduction faced by humans is infant and child mortality. Once an individual reaches adulthood, mortality rates are relatively low, with average lifespan ranging between 68 and 78 years among hunter-gatherers (Gurven and Kaplan 2007). Adults are also likely to find a mate, with virtually 100% of female and at least 90% of male hunter-gatherers doing so (see Volk and Atkinson (2008) for a brief review). The largest fitness challenges humans face, therefore, are first surviving their childhood and becoming reproductively successful adults and then themselves raising children to adulthood. Prior to modern history, infant mortality rates ranged from 25% to 40% and child mortality rates from 36% to 50%. These rates are very similar to modern hunter-gatherer groups (23% and 46%, respectively) (Volk and Atkinson 2008). Indeed, Hrdy (2009) notes that in many hunter-gatherer groups, a woman might give birth multiple times and never raise a child to adulthood.

Given the helplessness of infants, it is not surprising (though only recently acknowledged by scholars) that human mothers require the help

of others in raising offspring. Human mothers are remarkable in their propensity to allow others to interact with infants, even immediately after birth. This is not the case with other great apes, who will not allow any adult contact with infants until 3–6 months following birth (Hrdy 2009). Hewlett (1991) found that among many foraging societies, for the 20–50% of the time an infant is held, it is held by someone other than the mother, usually a close female relative or trusted caretaker.

There are conflicting thoughts on the importance of paternal investment, but collectively, they show that in contrast to mothers, fathers have less impact on child survival (Sear and Mace 2008). However, Gray and Anderson (2015) reviewed the influence fathers have on their children and concluded that paternal investment is typically resource-based (e.g., financial) and may impact on children's survival, health, socio-emotional outcomes, social competence, and educational attainment. Thus, while paternal investment does not seem to affect child mortality rates, Sear and Mace (2008) reported in roughly one-third of the studies where they examined paternal death that father's absence increases the likelihood of child death, but only for a limited time following the father's death.

The question of who keeps children alive then becomes a vital question, and Sear and Mace (2008) after examining 45 studies of kin-child-rearing patterns among people living in nonindustrialized groups, found that after mothers, maternal grandmothers have the largest effect on child survival. Hawkes et al. (1997) found that among Hadza hunter-gatherers, seasonal fluctuations in foraging returns among women predicted variations in child weight for non-nursing mothers. For nursing mothers, the foraging returns of the maternal grandmothers had a positive effect on the child's weight gain. Researchers in the USA have found that among kin, the majority of caretakers are single, African-American grandmothers (Cuddeback 2004), while in the UK, it is married white grandmothers (Aldgate and McIntosh 2006; Farmer and Moyers 2008; Hunt 2003).

Following mothers and maternal grandmothers, it is females in the group who invest

the most in childcare. Barry and Paxson (1971), using a controlled sample of 186 societies, found that after mothers, the principle companions and caretakers of children were adult female relatives, then female children, and then other females. Crittenden and Marlowe (2008) documented that among the Hadza, while female kin are most likely to engage in allomothering behavior such as holding an infant, female nonkin also assist more than males. In their review, Weisner et al. (1977) repeatedly stated that when care is needed, it is a woman more than a man, even if she is more distantly related, who is preferred. Likewise, as mentioned, in foraging societies, when a woman's gathering production decreases after the birth of a new child, the slack is most often picked up by female relatives and then friends (Hill and Hurtado 1996).

Female assistance in childcare and food provisioning begins at a young age. Older children in Bwa Mawego in Dominica take on adult domestic tasks, and in some households, girls around 12 years of age spend as much time in domestic activities as adult women (Quinlan et al. 2003). This activity does not only include childcare and overall relieves mothers' domestic burden which allows them to spend more time caring for their children. Similarly, among the Abuluyia females were the caretaker of small children more than twice as often as males (Weisner 1987). The same trend exists among the Kikuyu of Kenya (Leiderman and Leiderman 1974); Kikuyu child caretakers are usually 7–12 years of age, female, and may be siblings, cousins, or neighbors. They may care for the child for more than half the day, and while they may accompany the mother on various tasks, their primary responsibility is to take care of the child. This care occurs even if the mother is still nursing; the caretakers will take the child to the mother when it is hungry.

Based on the existing evidence from these societies, it seems probable that among humans, there has been selection for food sharing, work sharing, and by extension cooperation, particularly among mothers and grandmothers of young children (Hawkes et al. 1997), and other female group members (Kelly 1995). For

example, Silk et al. (2009) found females who formed strong bonds with their mothers and adult daughters experienced the highest rates of offspring survival (Sokol-Chang et al. 2017).

Conclusion

Overwhelmingly, childcare is prioritized and performed by women, even during childhood and until they are grandmothers. Due to this preference and the prioritization of the care of the child, women are much more reliant on other women, particularly female relatives like grandmothers. This reliance on a cooperative system has a crucial purpose: the care of one's offspring so as to safeguard their investment and, hence, the continuation of their genetic line. This is not only an important relationship but a labor-intensive one as well. When examined in its entirety, cooperation among women has been a vital factor in the survival of the species.

Motion Parallax

Olga Lazareva

Drake University, Des Moines, IA, USA

Definition

Motion parallax is a monocular depth cue produced by a difference in apparent direction and speed of displacement of the objects located at different distances from an observer, as that observer moves through the environment.

Introduction

Unlike binocular disparity, motion parallax is a monocular depth cue that does not require integrating information from two retinas. However, it is conceptually similar to binocular disparity in that the visual system must still detect the differences between two retinal images obtained successively rather than simultaneously (Rogers and Graham 1982). Motion parallax requires side-to-side (or translational) movement of the body or the head of an observer as depth information cannot be obtained from rotational movement alone. It has comparable precision to binocular disparity (Rogers and Graham 1982), and its use for depth perception is well documented for both humans and nonhuman animals.

Use of Motion Parallax for Depth Perception in Humans and Nonhuman Animals

As an observer moves through the environment, he or she will typically focus on some point in that environment (Fig. 1); in vertebrates, vestibuloocular reflex will trigger eye movements ensuring that the object will remain fixated on the fovea during movement. As a result, the features of the environment will form a bidirectional optic flow: The objects behind the fixation point will be

Motion Parallax, Fig. 1 Pattern of retinal motion created by the translational movement of observer to the left and fixation at the intermediate distance (F). The points located farther than fixation point (B_1 and B_2) will move in the same direction as the observer, whereas the points located nearer than fixation point (A_1 and A_2) will move in the opposite direction. Moreover, the speed with which each point moves across the retina will be proportionate to that point's depth from fixation; for example, the points A_2 and B_2 will be perceived as moving faster than the points A_1 and B_1

viewed as moving in the same direction as the observer, and the objects in front of the fixation point will be viewed as moving in the opposite direction. The speed of the perceived movement will be proportional to the distance from fixation point affording the relative ordering of the objects in depth. Sensitivity to motion parallax is already present in infants as young as 6 months (Condry and Yonas 2013).

Behavioral demonstrations of motion parallax have been carried out in several vertebrate species (barn owl, van der Willigen et al. 2002; gerbils, Ellard et al. 1984; Goodale et al. 1990; rat, Legg and Lambert 1990; rhesus monkeys, Cao and Schiller 2002). In addition, many birds (e.g., pigeons, chickens, gulls, and many shorebirds) also exhibit repetitive backward and forward head movements during walking as well as during landing ("head bobbing") that are thought to provide depth information via motion parallax. Supporting this hypothesis, Xiao and Frost (2013) have recently described neurons sensitive to motion parallax in pretectum of pigeons.

Similarly to vertebrates, many insects show behaviors that appear to produce motion parallax and result in better depth perception. For example, locusts and mantids periodically move their head sidewise prior to striking at a target; if the target is moved in the same direction as the head, then they tend to overestimate the distance to it suggesting that these movements are used as a source of motion parallax information (Kral 2003). Relatedly, bees and wasps circle around objects of interest, presumably using motion parallax to access their three-dimensional structure (Werner et al. 2016). Finally, fruit flies appear to use motion parallax generated by walking toward different objects to judge the distance to them (Collett 2002).

Conclusion

Depth information provided by motion parallax cues is as powerful and precise as that derived from binocular disparity (Rogers and Graham 1982). Unlike binocular disparity, motion parallax does not require binocular integration of information from overlapping visual fields and is therefore likely to be used by the animals with laterally located eyes, even when their visual fields have some degree of binocular overlap (Kral 2003).

Functional benefits of punishment; Reasons to punish wrongdoers

Definition

Elicitors of the desire to punish a wrongdoer.

Introduction

People are motivated to punish cheaters, but substantial disagreement exists among philosophers and social scientists regarding why. Evolutionary psychologists have been drawn to human punishment because sometimes it appears to be *altruistic punishment*, costly but non-beneficial to the punisher, making it an anomaly for evolutionary, functional explanations – that is, explanations of how the fitness consequences of a psychological phenomenon enable and shape its adaptive evolution. Functional explanations provide answers to the question of why humans punish – that is, they articulate aspects of human experience that make people want to punish wrongdoers. Evolutionary psychologists have proposed two main classes of functional explanations for human punishment. *Adaptationist* explanations assume that selection is driven exclusively by the punisher's *inclusive fitness* – the fitness effects of punishment on the punisher and the punisher's relatives (Hamilton 1964). By contrast, *multilevel selection* (or group selection) explanations assert that important selection occurs both on the punisher's inclusive fitness (individual level) and at the level of groups by enabling groups to compete against one another based on their complement of punishers. Adaptationists deny the importance of group-level selection, arguing it is too weak to influence the evolution of adaptations. A brief overview of the evolutionary psychology of human punishment provides substantial insight into what motivates humans to punish.

Adaptationist Approaches

Evolutionary theorists frequently used group-level or species-level explanations for biological adaptations until George Williams (1966) showed how individual-level selection could explain adaptive designs better than the prevailing group-level or species-level explanations (i.e., “good for the group” or “good for the species” explanations). Williams persuasively argued that group-level selection is weak compared to individual-level selection, so individual-level

selection should drive the evolution of biological adaptations. Williams not only undermined the credibility of group-level explanations, he also placed a foundational emphasis on the importance of articulating design features of adaptations. This emphasis developed into the form of evolutionary psychology known as *adaptationism*, an approach to evolutionary psychology that relies exclusively on individual-level selection in an empirical search for theoretically derived, a priori characterized design features of adaptations that comprise human psychology. Adaptationism has produced many complementary explanations and predictions regarding what factors motivate people to punish wrongdoers.

Seeking Better Treatment

According to *social exchange theory*, people use punishment as “a bargaining strategy” to enhance subsequent outcomes from their reciprocal interactions with specific individuals with whom they have potentially long-standing relationships (Krasnow et al. 2012, p. 3). That is, punishment modulates later behaviors of relationship partners to provide increased, direct benefits to the punisher. From this perspective, people forage for social exchange partners, using reputation information about how potential partners treat others as a cue to how they might themselves be treated, but preferring to use information about actual treatment by the person toward themselves if available. People invest in relationships hoping for long-term payouts. Such investment includes punishing defection when detected and directing punishment only toward those with whom a long-standing relationship can be expected so that punishment costs can be recaptured through subsequent benefits from that person. This perspective makes the surprising prediction that people will prefer to interact with cheaters more after they have punished compared to before they are punished. This is because punishment is theorized as an attempt to negotiate for better treatment. If however the actor perceives that prior losses are unlikely to be recouped by better outcomes later, the theory predicts the actor will abandon the relationship rather than paying costs to punish. By this approach, people are more likely to punish

someone who defects against them but is expected to continue as a long-term relationship partner but unlikely to punish someone who wrongs another person (a third party) or whose relationship the person is abandoning.

Social Relationships

Lieberman and Linke (2007) argued that an actor’s punitive motivation should be moderated by the degree to which an actor’s biological fitness is tied to others. For example, *inclusive fitness theory* shows how an actor’s fitness is tied to genetic relatives (Hamilton 1964). A brother’s children increase inclusive fitness and more so per child as compared to a cousin’s children. This is because we share more genes with a sibling than a cousin. Inclusive fitness is important for punitive motivation both because punishing a relative reduces one’s own fitness and because one’s fitness is reduced more when the victim is a relative compared to a nonrelative. Lieberman and Linke (2007) also argued that social exchange happens more with members of coalitions and in-groups and less with out-group members, so people should be more concerned with the welfare of coalition and in-group members. In summary, punitive motivation is moderated by the degree of genetic and social interdependence of the punisher with both the perpetrator and the victim: punitive motivation is stronger when victims are more interdependent and when perpetrators are less interdependent.

Reputation

One context in which apparently anomalous altruistic punishment occurs is when people pay costs to punish unknown third parties with whom the punisher expects no future interactions through which costs paid to punish the wrongdoer could be recouped. Kurzban et al. (2007) identified a means by which other sources of benefits and cost avoidance could be reaped by punishers of third parties even in such circumstances. They argue that punishment is costly due to dangers such as retaliation, making punishment itself a *costly* and therefore an *honest signal* – reliable source of information for observers that the punisher is willing and able to punish transgressions.

By punishing wrongdoers a punisher can develop a reputation as being someone who would be costly to mistreat. Kurzban et al. (2007) proposed that reputation benefits of punishment resulted in evolutionary selection for punishment-related adaptation. In particular, they predicted and found that punitive motivation is greater in the presence of an audience.

Offsetting Fitness Differentials

The exceptional cooperativeness observed in human groups is a theoretical problem because human groups produce benefits for members, but members who do not contribute to group efforts while still taking benefits – free riders – would have greater fitness outcomes than those who do contribute. Price, Cosmides, and Tooby (2002) argued that compared to contributors, free riders enjoy a *fitness differential* over contributors. The fitness differential is equal to (a) the costs paid by contributors, added to the (b) benefits free riders take greater than those received by contributors. This fitness advantage must be eliminated for adaptations enabling collective actions to evolve. Price et al. (2002) argued that *punitive sentiment* is an adaptation that evolved to offset these fitness differentials in the context of collective actions. Punitive sentiment is activated by free riders, detected as those “who (1) benefit from a collective action, (2) could have contributed . . . without incurring a cost disproportionately greater than their share of the expected benefit, and (3) did not expend adequate effort towards the collective action” (p. 206). Punitive sentiment’s output is “desire that the target of the sentiment is harmed [and perhaps] that (1) the target be aware of being harmed, (2) the target know why, and (3) others be aware of the reason for punishment” (p. 206). Indeed, participant punitive motivations tracked these and not other variables in response to free riders failing to contribute to a group-defense collective action (Price et al. 2002).

Recruiting Labor

Another perspective that argues punishment is motivated by free riding was provided by Krasnow, Delton, Cosmides, and Tooby (2015). They proposed that punishment can be considered

a labor recruitment method: it can transform would-be free riders into contributors. Krasnow et al. (2015) demonstrated how this could work using individual-level selection in agent-based modeling by enhancing the biological plausibility of model features, such as allowing agents to punish only some defections to avoid excessive costs of overpunishing as occurs when all punisher agents punish every defection, by allowing free riders to become cooperators rather than merely endure fitness reduction while continuing to free ride and by allowing agents to interact with members of other groups to enhance the strength of natural selection. Finally, agents remembered who punished them in the past and selectively cooperated when in the presence of prior punishers.

Multilevel Selection Approaches

As mentioned above, in the 1960s, George Williams largely undermined the scientific legitimacy of group selection theory. Over the last few decades, however, evolutionary scholars have reconsidered the issue. Sober and Wilson (1998) convincingly demonstrated how, mathematically, natural selection could in fact happen at multiple levels, including the group level, within a narrow set of circumstances. They further argued that human morality, including punishment, might be comprised of adaptations formed in part by group-level selection.

The problem for explaining group-level selection of human punishment is articulating how selection could favor individuals who pay costs to punish wrongdoers when the punisher himself or herself would not receive extra benefits as a result of the punishment compared to group members who did not punish. The group-level selection solution, in brief, is that (a) groups with more norm-compliance-enforcing punishers are more cohesive and functional than groups with fewer punishers and so (b) groups with more punishers outcompete and displace groups with fewer punishers, resulting in (c) a relative increase in the number of groups with more punishers, and therefore (d) punishers increase in number overall

despite a reduction in the number of punishers within groups (because within groups such punishers are at a disadvantage relative to non-punishers). That is, punishers proliferate because punisher-rich groups become more common and spread faster than punisher-deficient groups, despite punishers become less common than non-punishers within groups.

Punishing Norm Violators

One prominent multilevel selection theory of human cooperation and punishment is *cultural group selection* (Richerson et al. 2016). According to cultural group selection theory, group-level selection is enabled by diverse, culturally inherited social norms and institutions that produce substantial between-group differences, which in turn impact competition among groups. The phenotypic differences across groups can have strong impacts when groups compete with one another, enabling genetic selection on even small amounts of genetic differences between groups, a form of gene-culture coevolution. Punishment plays multiple important roles in this theory. Punishment of deviant behaviors increases phenotypic homogeneity within groups by enhancing conformity to group-specific norms, which also increases phenotypic heterogeneity between groups. Punishment, sometimes as prescribed by cultural justice institutions such as religion, also enhances within-group cooperation and helps solve public goods dilemmas. Finally, within groups punishment decreases fitness for genes related to antisocial behavior and increases fitness for genes related to prosocial orientation, another case of gene-culture coevolution. Core claims of cultural group selection theory were supported by a study looking at anonymous costly punishment and cooperation across 15 diverse societies. It found that people tended to punish unfair offers in all societies, but critically cooperation was higher in societies whose members punished more (Henrich, et al. 2006).

Conclusion

Evolutionary psychologists have developed many explanations regarding why humans are

motivated to punish wrongdoers based on functional considerations of punishment. Explanations relying on individual-level selection focus exclusively on effects of punishment on the punisher's inclusive fitness. From this perspective, people are motivated to punish others in order to (a) negotiate for better treatment; (b) protect the fitness interests of themselves, their relatives, and their in-group members; (c) develop a reputation that deters defection; (d) offset fitness differentials that free riders reap over contributors in collective action; and (e) recruit labor in collective actions. These explanations are complementary – all could be true – as could the more controversial group-selection explanations, which argue that people are motivated to punish norm violators to enhance their group's ability to compete with other groups.

Definition

Early speculative hypotheses concerning the origin of spoken language proposed by Friederich Max Müller.

Introduction

Müller was a German philologist who proposed some early theoretical formulations concerning the origins of language. After the publication of the *On the Origin of Species* (Darwin 1859), Müller was fascinated of the idea of human evolution. The tradition of giving disparage names

to the theories regarding how language evolved commenced by him and this was an important factor in his campaign against Darwin's evolutionary theory. Müller (1877) established associations between Darwin's evolution on humans and many other ideas about development, and he concluded that languages are subjected to historical radical change. However, he later realized that he underestimated Darwin's arguments and his suggestions concerning the history of human evolution. In 1864, Müller presented his *Lectures on the Science of Language*. In this period of time, he started to reevaluate Darwin's theory. In his book *The Descent of Man*, Darwin had a section about language, in which he proposed his own theories about the evolution of language. Müller had different ideas about how language emerged, and therefore, he talked in public about "Mr. Darwin's Philosophy of Language" in 1873 (Knoll 1986).

In these talks, Müller suggested that the language faculties of humans are distinguished from other creations; therefore, it was impossible that the human development evolved from a lower form without language acquisition. His point of view was supported by his opinion that the linguistic roots are considered the original building blocks of language. In his *Lectures on the Science of Language*, he proposes that Indo-European verbal communication had developed from hundreds of verbal "cells." Müller hypothesized these linguistic roots as fundamental of the theory of mind. He assumed that they establish the principles for the Kantian intellectual classifications used by the mind to establish cognizance out of raw sense of perception. This capacity of the individual's mental structure separated man from animals since it formed the basis of man's exclusive capacity to form a concept and think rationally. Without these capacities, neither language nor thought was possible. Müller concluded that because animals do not have this intellectual structure, their evolution into humans was impossible (Müller 1877). In 1861, Max Müller published a list of theoretical concepts concerning the origins of language. He later abandoned most of his theories which include the bow-wow

theory, the pooh-pooh theory, the ding-dong theory, the yo-he-yo theory, and the ta-ta theory.

Bow-wow Theory

The overall idea of the bow-wow theory is that the beginning of language can be linked to the era when the progenitors begun to mimic the sounds in their natural environment, a process called "onomatopoeia." The natural world was of paramount importance in the origination of language since the sounds of animals played a significant role in the invention of the vocabulary used in verbal communication. On the one hand, Thorndike (1943) was doubtful about the credibility of this theory as the beginning of language. On the other hand, recent studies support that being able to mimic sounds in the natural environment was of paramount importance in the evolution of language (Malle 2002).

A major drawback of this theory is the fact that people use different words to describe the sounds of animals according to their country and more specifically due to their language. For instance, the sound of a pig can be translated differently across the countries. In English a pig makes the sound "oink-oink"; in Russian it makes the sound "hyru-hyru," while in Chinese it makes the sound "oh-ee-oh-ee." Therefore, the sound and pronunciation of the words are not similar among the different languages. Another challenge is that there are few onomatopoeic words in the languages worldwide. In case the theory was credible, then it should have plenty of words out from the basic rule of onomatopoeia. The hypothesis that language is determined by how a person interprets a sound was rejected, since there are many languages and nobody can suggest that human vocabulary arose from these sounds (Thorndike 1943).

Ding-Dong Theory

The idea behind the ding-dong theory is sound symbolism which is a non-arbitrary connection

between phonetic features of linguistic items and their meanings. Max Müller proposed the ding-dong theory by stating that meaning comes from sounds. According to this hypothesis, the origin of language emerged evolutionary with the names our ancestors gave to objects, activities, and natural occurrences after an identifiable sound associated with it in real life (Mandavilli 2016). An important characteristic of this notion is the fact that words having high front vowels were used to name small or jagged objects in comparison to words having round vowel which were used to name large or round-shaped objects. It is suggested that people used sound symbolism to give meaning to words through onomatopoeia, which is the formation of a word by the imitation of a sound made by or associated with its referent in real space and time. “Boom,” for example, was the word given for explosion (Mitchell et al. 2013).

A major drawback of this theory is that onomatopoeic words are not the same in every country because the sound and pronunciation of the words are not similar among the different languages. People in different nations used their onomatopoeic words which are formed in regard to how they interpret different sounds. These words are a very limited part of their vocabulary since many ideas such as love, hate, harmony, and the sea do not make any noise. Thus, the relationship between meaning and sound is not established by any convincing evidence. For this reason, this theory was later abandoned by Max Müller (1877).

Pooh-Pooh Theory

The early speculative language theory of pooh-pooh refers to the notion that language emerged from unintentional vocal responses to agony, fright, astonishment, enthusiasm, satisfaction, or other emotions (Barber 1965). Although animals produce sounds as well, language is unique only to humans. “Ouch!,” “Aaah!,” and ‘Wow!’ are some examples of the unintentional vocal responses emerged from this hypothesis. This

theory can be found in the literature as “the expressive theory,” “the interjectionist theory,” or “the expressions of emotions theory” (Barber 1965). Max Müller supported the pooh-pooh theory for a while, but later he abandoned it (Müller 1877).

The notion of the pooh-pooh theory that language has many emotional exclamations has been widely criticized by many reviewers. It has been argued that the explanations provided by this theory constitute a very limited part of the vocabulary of different languages. Further, the various languages worldwide have different interjections. For instance, in English pain is “ouch” while in Greek it is “aou.” Therefore, it is indicated that sounds could have been different if their origin was from interjections. To conclude, although early human beings could use words based on interjections, these may have been ultimately overruled by more sophisticated and abstract terms (Mandavilli 2016). Finally, it is important to emphasize that although animals react to the sudden feelings they experience using sounds, they didn’t develop language as human beings did.

Ta-Ta Theory

According to Richard Paget, who was specialized in speech science and the origin of speech, the ta-ta hypothesis supported that speech and the development of sound were produced to endorse the hand and body movements of the individual. So as to better demonstrate the meaning behind the gestures, these sounds developed different words or combinations of sounds unavoidably leading to speech patterns (Paget 1930). For instance, when a person would say ta-ta, he was basically saying good-bye with his tongue. At some point, this theory was even supported by Charles Darwin (Mandavilli 2016). In the literature, there are several theories such as the oral gesture theory and the chew-chew theory that support the idea that the origin of language begun from early human gestures made from their mouth. It is of paramount importance,

though, to understand that it is not feasible to explain the origin of some words using the ta-ta theory.

A major drawback of this early theory on the origins of language is the fact that in order for people to be able to communicate between them, they must see each other in person. Also, there must be daylight, or firelight, and with nothing blocking one's view. In the case of hand gestures, it is important that hands are free from doing something else (Meir et al. 2010). Last but not least, in order for this hypothesis to be the origination of communication, it required a number of gestures be in place already for humans to imitate with their mouth gestures, but it didn't explain how these gestures arose in the first place.

Yo-He-Yo Theory

Verbal communication commenced as growls, moans, and rhythmic chants which occur from the overwrought efforts of ancient menfolk to move a boulder or heave a rock, as it is suggested by the yo-he-yo theory (Mandavilli 2016). Every time these people were working hard to move something heavy, they produced a sound which slowly developed into words such as "heave" and "lift." Therefore, if they didn't want to memorize their favorite growl-sound and use it over and over again, this sound would seem to be random. However, these growls would not be accounted as words in a lingual meaning since they would seem unlikely to fall into consonant-vowel patterns (Rice 1976). The yo-he-yo theory does, however, have a benefit since it is responsible for the inducement, the cause, and the aim of the language. It describes language as emerging from a need to communicate and for making the engagement among men possible in organized activity, rather than seeing language resulting from a cave dweller imitating an animal's howl to assist him while he was away for his dinner (Barber 1965). The yo-he-yo theory can be found in the literature as "Yo-heave-ho theory" and "Social interaction source," all of them proposed that the origin of speech begun as growls and moans (Mandavilli 2016).

Notwithstanding the above, evolution plays an important role since it claims that human society developed gradually because men began thinking of new things to do and began doing them collectively. What makes this theory interesting, however, is the query of what motivates the speechless cavemen move a boulder in the first place since language emerged from the growls and moans of their teamwork. Unfortunately, the origin of grammatical structure is not explained or how a social system got started void of language (Rice 1976).

Conclusion

It is a matter of fact that language is a human trait. All efforts to explain how language emerged have failed because of the absence of knowledge concerning the origin of any language. An important factor for the inability to acknowledge the origin of language is because none of the animals possesses any transitional form of communication. As a consequence, Muller could not differentiate between humans' linguistic faculties and the growls or sounds of animals. Also, the cultural roots of various hand gestures did not suggest verbal communication. Last but not least, most of his theories did not explain the origination of different ideas or things that do not produce any sound, and this resulted to a limited vocabulary of the languages. As a result, there could not be an explanation of the origin of names of such concepts, if his theories were chosen as the origin of language.

Müllerian Mimicry

Hannah M. Rowland

University of Cambridge, Cambridge, UK
Institute of Zoology, Zoological Society of London, London, UK

Synonyms

Arithmetic mimicry; Müllerian association; Mutualistic mimicry

Definitions

When two or more harmful or unpalatable animals develop similar appearances as a shared protective device.

Introduction

Many prey possess chemical compounds or other noxious substances that they advertise to potential predators via conspicuous warning signals (Sherratt 2008). Mimicry describes the resemblance of one animal (a mimic) to chemically defended species (the model), such that a third animal (usually a predator) is deceived by the similarity. Mimicry is conventionally divided into two separate categories depending on the phenotype of the mimic: Müllerian and Batesian mimicry.

In Batesian mimicry, named for its discoverer, Henry Walter Bates (1862), an undefended harmless species evolves a warning signal (e.g., visual, auditory, or even behavior) that imitates a harmful model species. Batesian mimics gain protection against predators due to their being perceived as harmful. In contrast, Müllerian mimicry describes the phenomenon where two or more defended species, that may or may not be closely related and share one or more predators, mimic each other's warning signals. It is named after the German naturalist Fritz Müller who first proposed the concept in 1878.

A History of the Idea

In his travels in the Amazon, Henry Walter Bates (1862) observed that as well as palatable species evolving to resemble defended species, there were cases where a number of defended species evolved to resemble one another. He proposed that this was due to species sharing similar environmental conditions. However, Fritz Müller suggested an alternative reason. In one of the first clear mathematical treatments of natural selection, Müller hypothesized that to learn to avoid prey with a particular visual signal, predators must kill a fixed (i.e., density-independent) number of that prey. If true, resemblance between a number of prey species would result in a divided cost of educating the predator species. Consequently, an increase in the number of visually similar co-mimics spreads out the costs of predator education between the co-mimics, and Müllerian mimics enjoy strength in numbers: the relative risk of predation on each individual species is reduced. Hence, two defended species that have separate signals pay a higher mortality cost during predator learning than two species that, through mimicry, resemble each other. Although this idea initially met with opposition from Müller's contemporaries (see Ruxton et al. 2004), the benefits of shared resemblance of unpalatable species are now commonly accepted.

Müllerian mimicry has been explored comparatively, theoretically, and empirically (Sherratt 2008). Selection for color pattern similarity among mimetic butterflies in the wild is strong, and research in controlled laboratory settings has uncovered the selective pressures leading to signal similarity.

Examples of Müllerian Mimicry

Müllerian mimicry is common in nature, with perhaps the most obvious example being the black and yellow striping of bees and wasps (hymenopterans). Müllerian mimicry has also been documented in frogs, larval and adult lepidoptera, snakes, coleoptera, fish, and birds (Sherratt 2008). The most celebrated example of

Müllerian mimicry is observed in the heliconid butterflies of South America, which involves a large collection of similar-looking species – a “mimicry ring.”

There is a long and distinguished history of research on mimicry in heliconids. The Heliconiinae is comprised of 46 described species that all contain cyanogenic glycosides and have conspicuous brightly colored wing patterns – aposematism. Mimicry in *Heliconius* often involves convergence between species within the same genus, and frequently between pairs of species. For example, *Heliconius cydno* generally mimics *H. sara*/*H. sapho*, while *H. melpomene* always mimics *H. erato*. These latter two species are distributed throughout South and Central America, and mimic one another wherever they co-occur.

The Evolution of Müllerian Mimicry

There have been two schools of thought on how mimicry evolves. One proposes that shared resemblance evolves through gradual change, the other suggests that mimicry evolves by large mutational leaps toward similarity, followed by gradual evolutionary fine-tuning of the mimic's appearance toward the model. The second proposal, called “the two-step hypothesis,” is supported by recent comparative genomics research showing that large-effect chromosomal inversions give rise to different morphs, but that the evolution of accurate mimicry likely requires a more gradual accumulation of multiple genetic changes (Nadeau et al. 2016). The two-step hypothesis relies on the assumption that predators generalize their avoidance between models and mimics with a level of shared resemblance (Leimar et al. 2012).

Müller's Idea About Predators Attacking a Fixed Number of Prey During Learning

One of the specific assumptions of Müller's theory is that predators must attack and consume a fixed number of each distinct defended species

before learning to reject them. To date this hypothesis has only been tested in laboratory experiments with captive predators. There has been no support for the “fixed n” idea. In fact, several experiments have reported increases in the numbers of unpalatable prey attacked as the abundance of that prey type increases (Sherratt 2008). This is perhaps unsurprising, because animal cognition is rarely expected to be as simple as learning by a fixed amount of experience. An outstanding question of fundamental importance is how predator learning proceeds in a wild setting – how often does a predator meet a model or a mimic in a season, or during its lifetime, and does it ever learn to completely avoid aposematic prey? Questions like these are challenging to address, but could reveal more of the underlying dynamics of mimicry.

Evidence That There Is Selection for Signal Similarity

Several field studies have found evidence for the benefit of sharing a common warning signal (reviewed by Sherratt 2008). In mark-recapture experiments on *Heliconius* butterflies, wild avian predators select against rare and unfamiliar warning signals, and locally common signals have better survival. For example, Mallet and Barton (1989) transferred *H. erato* across the hybrid zone and monitored the survival of the transferred individuals compared to control species which were marked and released. The authors found that more of the rare artificial migrants were attacked and less recaptured than controls. Selection for color pattern similarity among mimetic butterflies in the wild was strong.

However, evidence that predators select for increasing signal similarity is less clear when research is conducted in the laboratory. By observing the foraging behavior of wild-caught captive great tits (*Parus major*) on artificially defended prey, many researchers have found that co-mimics with visually dissimilar appearance can still benefit from strength in numbers, with predators generalizing their avoidance to dissimilar signals (discussed in Rowland et al. 2010). However, mimicry *can* provide substantial

protection during predator learning in the lab, and in the manner proposed originally by Müller, especially if prey are visually distinct and not easily generalized (Rowland et al. 2010), of if the system is more similar to the real world. In a study by Ihalainen et al. (2012), great tits foraged in simple or complex prey communities. Ihalainen et al. found that predator learning was slower and more costly to nonmimetic prey in visually complex prey environments. Therefore, mimicry would be beneficial in complex prey communities, because of the costs of predator education, just as Müller predicted. Interestingly, many studies have found evidence that pattern similarity might also benefit prey in the later stages of the learning process (note that Müller’s ideas are about naïve predators). These findings in conjunction with the field experiments discussed previously suggest that once birds are familiar with a particular warning color or pattern, experienced predators can also select for pattern convergence (Rowland et al. 2010).

Species Differences in Defensive Chemical Concentrations, and Its Consequences for the Evolution of Müllerian Mimicry

Several authors have proposed the existence of a “mimicry spectrum,” of which Batesian and Müllerian mimicry could be thought of as the extremes. This spectrum comes from the continuous range of chemical defense levels of mimics, and the role of predator psychology in selecting for signal similarity (Sherratt 2008). It is well documented that different predators vary in their ability to overcome the chemical defenses of aposematic prey, and it has been suggested by some authors that this can produce a hybrid between Batesian mimicry and Müllerian mimicry. In cases where predators profit from attacking prey with lower levels of chemical defense, model species may not benefit from coexistence with a visually indistinguishable but less-defended mimic, and lose protection when the mimic form is abundant. Therefore, mimicry between two species can be parasitic and Batesian-like (or quasi-

Batesian) and not necessarily mutualistic and Müllerian. Quasi-Batesian mimics could face much stronger selection for signal accuracy than might Müllerian co-mimics (Sherratt 2008).

Müllerian Mimicry and Speciation

Differences in color patterns between co-mimics can lead to reproductive isolation via pre- and post-zygotic mechanisms. This is because recombinant wing patterns are usually nonmimetic and are selected against by predators – a form of hybrid incompatibility. Furthermore, model species are also less attracted, or not attracted at all, to hybrids as potential mates – a form of post-zygotic isolation. Furthermore, *Heliconius* species' mate preference for similar wing patterns is also genetically linked to the genes that underlie the wing color that distinguishes them from other species. This reinforces post-zygotic isolation.

The Molecules Behind Mimicry

Research on heliconius butterflies has unraveled the genomic bases of how mimicry evolves and varies. Advances in sequencing technology and comparative genomics, coupled with recombination mapping have enabled scientists to accurately pinpoint candidate genomic regions responsible for mimicry.

The major loci involved in wing pattern development are collectively referred to as the “wing patterning toolkit” (reviewed in Kronforst and Papa 2015), and comprise: *optix* – a transcription factor that places red patches onto the wings, as well as the black regions on the central part of the wing; *WntA* which is associated with melanization of the fore and hind wing; *poik* – a cell-cycle regulator that is involved in patterning of the central areas of wings, and a gene, *cortex*, that probably regulates pigmentation patterning (Nadeau et al. 2016).

Conclusion

The study of mimicry has been a test bed for the theory of natural selection. Since Müller's

hypothesis, the molecules responsible for mimetic resemblance have been uncovered. We now also have evidence that mimicry evolution is driven by predation pressure: species exposed to the same predators benefit from sharing warning signals. However, there is still a need to investigate how avoidance learning and predators' response to mimetic symbols occurs in the wild. This is an important question because if predators learn to avoid unpalatable prey differently in simple and complex communities in the lab, then how does learning proceed in natural conditions where we don't know how often they meet aposematic prey, if they meet them sequentially or simultaneously, and if they ever fully learn about aposematic prey. There is still much to discover.

Multilevel Selection Theory

Kevin M. Kniffin
Cornell University, Ithaca, NY, USA

Synonyms

Group selection; Inclusive fitness theory; Individual selection; Kin selection

Definition

Theoretical framework that presumes that selection can occur at an array of organizational levels from the gene upwards.

Multilevel Selection Theory

Multilevel Selection (MLS) Theory is the synthesis of individual selection as popularized by researchers including Williams (1966) and group

selection as championed by researchers including DS Wilson (1975). More precisely, MLS theory offers a pluralist and flexible analytical framework that recognizes that selection occurs at different levels of organization as a function of context. As Wilson and Sober (1994) illustrated, when there is both phenotypic uniformity and shared fate at a given level of organization, then selection can be expected to occur. Consequently, if there is no phenotypic uniformity or shared fate among individuals in a given set of individuals, then one would expect selection to occur at the level of individuals. On the contrary, if individuals in a given set do share a common fate with one another and demonstrate phenotypic uniformity, then one would expect selection to occur at the level of sets wherein sets are being selected across evolutionary time relative to other sets in a given population of sets.

In the case of humans, there is obviously not genetic uniformity within any groups (outside of twin-pairs); however, there can certainly exist phenotypic uniformity as well as shared fate within groups since cultural transmission is dynamic and not isomorphic with underlying genetic variation (Wilson and Kniffin 1999). Indeed, Wilson and Sober (1994) review the fact that it is undisputed that genes function as “replicators” as a fundamental level of evolutionary accounting; however, conditions can and do emerge whereby units of organization above genes and above individuals can emerge and function as “vehicles” on which selective retention can occur. For example, Kniffin and Wilson (2010) review three case studies where group-level incentive structures within a population allocated rewards so that individuals would benefit if they served group-level interests.

Among non-human species, there exist numerous laboratory demonstrations whereby selection at group or community levels has been cultivated – often for beneficial outcomes. For example, Swenson et al. (2000) successfully selected for soil ecosystems that more effectively degraded an environmental toxin. More recently, with the benefit of genetic sequencing technology, researchers have demonstrated that selection at the level of soil microbiomes can be effected in ways that yield valuable traits in economically important plants

(Garcia and Kao-Kniffin 2018; Panke-Buisse et al. 2015). Criticisms (e.g., Williams 1966) of group- or multilevel selection have traditionally acknowledged that it can be artificially effected but have been skeptical that it occurs in nature except for species where there is uniquely high genetic relatedness among individuals within groups (i.e., social insects [Seeley 2009]). Reviews of naturalistic evidence from species such as African buffalo indicate, though, that such dynamics are visible in naturalistic conditions (Prins 1996; Wilson 1997).

MLS theory has been the subject of contentious debate at various points over the past five decades partly because it has been central to debates on the evolution of altruism and selfishness where a variety of additional theories (e.g., kin selection and inclusive fitness theories) have been presented as competing frameworks. Consistent with the intention of MLS theory to be integrative and holistic of more specific theories, Wilson and Wilson (2007: 345) summarize the MLS perspective with the pithy set of statements that “Selfishness beats altruism within groups. Altruistic groups beat selfish groups. Everything else is commentary.” In other words, selection occurs at the level of individuals when individuals are selfish while selection occurs at the level of groups when individuals are altruistic within their own groups. Debate continues on these perspectives; however, there has, at least, been important refinements over the past five decades in how such positions are argued whereby (1) MLS theory offers an integrative framework that is inclusive of both individual- and group-level selection and (2) relatively new genetic sequencing technologies are increasingly facilitating a better understanding of the mechanisms through which selection at multiple levels (from the gene “upwards”) can be examined.

Definition

Copulate with more than one sexual partner.

Introduction

Empirical studies and theoretical models have used the number of sexual partners (i.e., the level of *multiple mating*) as a proxy for lifetime reproductive success (RS) or fitness. This is not surprising considering the close connection between mating and reproduction. In the case of males, the relationship between these variables is considered positive, whereas for females an intermediate optimum is predicted (Fig. 1a). However, when males invest heavily in each mate an intermediate optimum is also expected (Fig. 1b). On the other hand, it is recognized that sperm competition, postcopulatory cryptic choice, and postcopulatory sexual conflict could strongly modify the relationship between reproductive success and number of mates (Shackelford and Hansen 2015). These processes could partially explain why in different human societies the high proportions of cuckolded males, resulting from female multiple mating, are not reflected in high rates of extra-pair paternity (Larmuseau et al. 2016) (Fig. 1).

The relevance of the number of sexual partners for evolutionary interpretations is also evident in

definitions of animal mating systems, which include the number of mates as an essential component. Mating systems are usually considered species-specific, although alternative strategies are included in recent discussions. Mating system definitions have been extremely helpful for organizing interspecific variation in, and identifying selective pressures acting on, reproductive behavior. Nevertheless, even when alternative strategies have been identified, each strategy encompasses individual variation in the number of mates due to strategic decisions, constraints, and chance. Hence, the study of individual variation in number of mates could provide interesting perspectives on the proximate causes and selective pressures acting on individual decisions, especially in species with a long reproductive lifetime, such as humans.

Identifying the Alternatives

When an individual reaches reproductive age she/he will face a number of lifetime options regarding the number of reproductive partners. In Fig. 2 these options are illustrated. An individual could decide or be able to copulate with just one mate or with multiple mates (the alternative of remaining virgin for life is also a possibility). The route taken could depend, for example, on the sex appeal of the individual or the amount of resources she/he controls. For example, an unattractive male or a male without resources could be constrained to mate with only one female, probably of low quality, or try an alternative strategy such as become a rapist. In addition, if he is able to get one female, he could just mate once (this would be the case if he is a rapist or if he is involved in a short-term interaction with the female) or establish a long-term relation in which he performs multiple *in-pair copulations* with the female (which could reduce, for example, the negative effects of female extra-pair copulations [EPCs] or increase the strength of the pair bond) (Fig. 2).

In contrast, if the individual is able, and decides, to copulate with multiple mates, she/he could opt for a series of short-term relationships in which she/he mates once with each partner

Multiple Matings,

Fig. 1 Relationship between individual reproductive success (RS) and lifetime number of sexual partners (number of mates). (a) Male RS is limited by number of mates, while female RS has an intermediate optimum determined by the costs and benefits of multiple mating. (b) Both male and female RS have an intermediate optimum determined by the sex-specific costs and benefits of multiple mating (in the example, the female optimum is smaller than that of males)

Multiple Matings, Fig. 2 Diagram showing the alternatives open to an individual female or male regarding lifetime number of sexual partners (number of mates)

(sequential multiple mating) or she/he could perform repeated in-pair copulations with each of a number of mates; a mixture of these alternatives is also possible, as when a female exhibits simultaneous multiple mating by establishing a long-term relationship with a male and, at the same time, having EPCs with other males (this could benefit the female if she improves the quality of her offspring by mating with a high-quality “lover” who fertilizes her eggs, while being supported by a male that provides better parental care than the attractive male).

Analyzing individual mating frequencies improves the ability to identify ecological and phenotypic constraints on multiple mating and thus to understand the selective pressures and adaptive traits affecting variation in the number of mates and of copulations. For example, several studies have focused either on multiple mating or in repeated in-pair copulations, but trade-offs between these variables (due, for example, to constraints in time or ejaculate production) have been rarely considered, as well as the influence of factors such as health or age on these trade-offs. However, as shown in the following sections, most evolutionary perspectives on human mating frequencies have used the traditional mating systems approach.

Multiple Mating in Humans: Patterns

Although most contemporary human societies practice socially imposed monogamy, this system often enables simultaneous multiple mating. An example of simultaneous multiple mating is EPCs in which sexual couples involved in long-term romantic relationships simultaneously seek EPCs with additional partners. EPCs are very common in humans, appearing approximately in 84 % of societies (Simmons et al. 2004; Anderson 2006). Nevertheless, its frequency and intensity of occurrence is highly variable. For instance, in the “Tsimane,” a forager–horticulturists society living in the lowland rainforests in the Beni region of Bolivia, 31 % of married males reported EPCs during the first 5 years of marriage (Scelza 2013). Similar rates were reported by the Himba

society wives, a seminomadic pastoral population living in the northwest corner of Namibia (Scelza 2013). Female EPCs are also common in several societies from Northwestern Europe and North America, with approximately 20 % of women reporting cases of sexual infidelities, slightly lower than those reported by men (Simmons et al. 2004). Nevertheless, in the “iKung,” a hunter-gatherer society from the Kalahari Desert of Namibia (Anderson 2006), EPC rates of 2–5 % have been reported, whereas in Hong Kong EPC rates of 8 % in men and 1 % in women have been reported (Anderson 2006).

Multiple Mating in Humans: Selective Pressures and Adaptations

The close relationship between mating and reproductive success, as well as the convergence and divergence of male and female reproductive interests, frequently will result in intense selection on male and female traits related to mating frequency and, thus, in adaptations to achieve optimal mating rates (Fig. 1). The RS of men is constrained by the number of fertile women they can mate with, but other factors, such as high paternity uncertainty, also could favor multiple mating in males as a way of increasing the probability of fathering at least some children. On the other hand, selection also can favor male traits that reduce multiple mating in females, such as sexual jealousy, mate guarding, and frequent in-pair copulation (Shackelford et al. 2006).

In the case of women, multiple mating could be selected to obtain genetic benefits for their offspring (Scelza 2013). For instance, female EPCs may allow producing offspring with higher heterozygosity, thus increasing their probability of survival, or offspring whose fathers are of better genetic quality. Moreover, female multiple mating could result in material benefits. For example, a woman could receive resources from each of their sexual partners, she could decrease the time to establish a new marriage when the previous relationship dissolves through death or divorce, or she can reduce infanticide risk (Scelza 2013). However, adaptive EPCs by women select for male

adaptations against female EPCs, such as different forms of punishment, including reductions in paternal investment or even homicide.

An intriguing aspect of human sociosexual behavior is why socially imposed monogamy is exhibited by most contemporary societies, instead of another mating system, such as polygamy, which could allow males and females to gain some of the potential benefits previously mentioned. In fact, most current societies have norms that sanction multiple mating (i.e., EPC), even though such sanctions also affect those who impose the norms (Hauert et al. 2007); for instance, most contemporary societies who practice socially imposed monogamy have a patriarchal origin and punish men (although usually not as hard as women) that incur in EPCs (Hauert et al. 2007). However, besides reducing cuckolding risks, other selective pressures could favor the development of norms against multiple mating. Human pathogens are a fascinating possibility. Exposure to sexually transmitted bacterial infections (STIs), such as syphilis, gonorrhea, or Chlamydia, may impose an enormous selective cost (Bauch and McElreath 2016), particularly in populations living in conditions similar to those experienced by humans during most of their evolutionary time, such as limited access to health services and contraceptive methods (Apari et al. 2014). In these populations multiple mating increases morbidity of STIs and thus the costs for individuals and their offspring, such as high rates of infertility and of mortality (Apari et al. 2014). In addition, there is evidence that seminal fluid proteins have a negative effect on the immune status of females, probably resulting from changes in the expression of immune genes in the cells of the female cervix following reception of a male ejaculate (Sharkey et al. 2012). Furthermore, persistent postmating immune changes produced by multiple mating can result in environments favorable for the invasion of other sexually transmitted pathogens, such as herpes simplex, human papilloma, and hepatitis B or C viruses (STVs; Sharkey et al. 2012). It is interesting to note that the negative effect of seminal proteins on female immune status could be increased not only via multiple mating but also as a result of repeated in-pair

mating, leading to the hypothesis that those seminal proteins evolved as a sexually antagonistic adaptation against female cuckoldry. Thus, norms against multiple mating could be favored not only as adaptations for increasing paternity certainty but also as mechanisms for decreasing the risk of STIs and STVs contagion (Bauch and McElreath 2016).

Conclusion

Multiple mating is observed in most human populations, although at different frequencies, and it seems likely that it has been present during most of the history of the species as attested by the psychological, physiological, and cultural adaptations observed in men and women. Sexual differences in benefits and costs derived from multiple mating indicate that sexual conflict over multiple mating is common. Although sexual selection probably had a strong effect in the evolution of multiple mating in humans, other selective pressures, such as those derived from diseases directly or indirectly related to sexual promiscuity, need to be carefully studied for a full understanding of the causes and consequences of multiple mating.

Definition

“Multiple Memory Systems” is a theory that is based on scientific and evolutionary evidence, which lead us to conceptualize memory, not as unitary system, but multiple systems that work independently, in synchrony, and/or in competition with each other.

Introduction

There are several memory systems, which have been identified (Poldrack and Packard 2003). Depending on the memory function(s) that are needed for the organism to encode, learn, maintain, or recall information, these systems are thought to be able to work independently, in unison/cooperation, or even compete with each other (Sherry and Schacter 1987).

They work independently when, for example, you are driving with memorized directions, given to you for a place in the city, while at the same time you are not forgetting the specific time that you have to attend an important meeting and you are concurrently contemplating the details of your presentation at the meeting.

The cooperation of memory systems is apparent, for example, when positive emotional memories come to you when you walk into a bookstore and the smell of pencils and school supplies hit your nose, and remember suddenly small details from your school years start coming back to you.

Their competition is evident in our everyday life as well. For example, a memory system responsible for encoding factual information could be “interrupted” by a competing memory system responsible for emotional information. For example, the memorized information for a neuro-anatomy test that you are taking in class right now is not very clear in your mind during the test, as you suddenly remember last day’s upsetting phone call from a friend.

We theorized that our memory and its systems have been evolving along with their associated structures in our brain. Our memory systems, which are defined as “...an interaction among acquisition, retention, and retrieval mechanisms

that is characterized by certain rules of operation...” (Sherry and Schacter 1987) are therefore evolved traits that are in place for improving our survival chances and reproductive success as a species. There are a few different approaches in categorizing and defining memory systems, but these approaches are not in contrast with each other, but coexist and represent different types of scientific approaches. Therefore, the neuroscientific approach will naturally approach the matter from a structural neuroanatomical worldview, while the evolutionary perspective will capitalize on the changes observed through the evolution of our species.

Neuroscientific and Cognitive Approach

Murray et al. (2017) postulated that neuroscience and its subspecialties, such as neuropsychology, neuroimaging (e.g., functional Magnetic Resonance Imaging-fMRI, spectroscopy, Computerized Axial Tomography-CAT, just to name a couple well-known neuroimaging methods), neurodevelopment, pushed towards learning massive information about our brains following centuries of knowing minimal information about our brain and its function. This vast amount of knowledge generated more research and thoughts about our memory and its functioning, and therefore, we started developing evidence supported hypotheses and theories about our brain’s memory systems.

In addition, the associations between brain damage in certain locations and the followed behavioral disorders (as in the case of H.M., the famous patient with global amnesia) allowed making inferences about memory dysfunctions and brain areas associated with certain memory systems. The first and second world wars (followed by numerous other regional wars) produced a large number of brain damaged individuals, who needed to be cognitively assessed and, in more recent years, scanned for deciphering the presence and extent of brain damage. These individuals, via their acquired brain injuries, taught us a lot about memory, brain areas that control memories, and in return directed us to theories about memory systems. After all, memory is one of the

first cognitive functions, which are affected by brain injuries (Rabinowitz and Levin 2014).

In neuroscience, it is widely accepted that the following memory systems exist (Murray et al. 2017):

1. A memory system that involves our personal learned experiences and habitual information is associated with our basal ganglia. For example, our memories about the name of a location that means a lot to us or a movie that we really liked.
2. Our explicit memories are mostly connected with functioning in medial structures of our temporal lobes (medial structures). For example, factual information about statistical formulas that you learned for a test.
3. Emotional information and emotional memories are mostly correlated with our amygdala. For example, negative emotions that are brought up after visiting a hospital that reminds you of health issues that you had in the past.
4. Memories about movement and motor processes are connected with the function of our cerebellums.
5. The priming of behavior is connected with our sensory cortices.

A cognitive science and cognitive psychology take on the memory systems follows a similar world view with the neuroscientific approach with mostly semantic differences between the two. Here three memory systems are recognized. Each memory system receives sensory and emotional information and in return, each memory system produces its output. Here are three memory systems:

1. The Procedural Memory System, which is highly associated with the cerebellum and caudate nucleus, processes action-related memories and memories related to motor processes, such as cycling (Hsiao and Chai 2003).
2. The Declarative/Explicit Memory System is mainly associated with the hippocampus and is responsible of mindful encoding of information and memories of facts and events. Our semantic (e.g., news pieces) and episodic

memories (private living experiences) are processed here.

3. Amygdala is associated with our Emotional Memory System, and therefore it is related to our emotional memories.

Evolutionary Science Approach

According to evolutionary cognitive scientists (Murray et al. 2017), there are seven memory systems that were developed through human evolution. These are:

1. Our Reinforcement Memory System, which describes memories that are made stronger or weaker via reinforcement schedules. For example, memories that are strengthened because they are associated with rewards (e.g., remembering your partner's birthday strengthens your relationship).
2. Our Navigation Memory, which we developed in order to store locations and directions to help us find our way in our environment. For example, remembering how to get around and short cuts in a large Business Building.
3. Our Biased Competition Memory, which compares new information we come across to older stored information in order to identify the need for new learning or expanding on older learned information. For example, in a child, learning that a dog is not a larger cat may create a new memory category for dogs.
4. Our Manual-Foraging Memory, which developed after we started walking on two legs and our arms and hands became free for action and collaborate better with our vision on visual-spatial integration tasks. This is the memory that allowed us to learn how to farm, hunt, and work manually in an environment that requires visual motor integration.
5. Our Feature Memory, which stores newly learned information according to its individual features, such as color, size, weight, surface. For example, learning that bears with black and white large spots are pandas.
6. Our Goal Memory, that helps us use stored and new information with our goal-directed

behavior. For example, recalling what history taught us may lead to better politics, in order to avoid wars.

7. Our Social Subjective Memory that encodes information about how we view our selves and how we view others in order to maximize our self-awareness and social behavior. For example, our stored self-image and awareness of our social self is compared with other more social individuals, who seem better than us, and this leads us to improve our social behavior.

Conclusion

There are multiple memory systems and in theory, at least, organize our memories according to their nature, type, and brain location(s) that they are stored or processed. Our Memory systems could work in full cooperation with each other, individually, or compete with each other in our everyday lives. All memory systems exist in order to help us survive and succeed as human species. In order to fully comprehend and keep learning about our memory systems and their evolution and value, we need to work in a multidisciplinary environment that combines knowledge from numerous sciences such as (just to name a few) cognitive psychology, neuroscience, neuropsychology, evolutionary science, and neuroanatomy.

Different approaches in defining and identifying memory systems are not in competition with each other but coexist and are completing each other. For example, a neuroscientific approach to memory systems would certainly focus on brain loci, while an evolutionary approach to memory systems would concentrate on how our memory systems changed through our evolution to better serve our survival and reproduction needs.

Murder

Nicholas Primavera
SUNY New Paltz, New Paltz, NY, USA

Synonyms

[Homicide, to kill](#)

Definition

Taking the life of another living being unlawfully.

Introduction

The act of murder has existed as long as humanity itself has existed. It is very unlikely, if not impossible, that murder will cease to be an issue during the course of humanity's future.

An Evolutionary Overview of Murder

Murder, or the act of killing another, has been around since the beginning of time and most likely well before recorded history. The act of killing another human carries the greatest cost to

the victim. After all, the recently deceased is no longer able to provide for themselves or their surviving families. From an evolutionary standpoint, this would be the greatest cost to one's fitness; premature death without reproduction is a significant issue. It is important to note, however, that humans are not the only beings that commit murder. The act of murder has been observed within chimpanzees and other primates as well. Researchers Watts and Mitani found that "Observations support the arguments that infanticide has been an important selective force in chimpanzee social evolution and that females with dependent infants can be at great risk near range boundaries, but why male chimpanzees kill infants is still uncertain" (Watts and Mitani 2000).

Historically, there has always been some form of punishment for the act of killing. Some of the earliest recorded history showed records of punishment, including the famous Hammurabi's Code, which was recorded to approximately 1754 BCE. Hammurabi's Code covers one law pertaining to murder which states, "If the wife of one man on account of another man has their mates (her husband and the other man's wife) murdered, both of them shall be impaled (Claire n.d.)." This example demonstrates that ancient civilizations had laws in place to discourage and punish people from committing murder. In ancestral times, it is quite possible that the act of murder carried consequences as well. Ancestral groups are anticipated to have travelled within groups of approximately 150; therefore consequences to murder would have been severe. For example, the murderer could potentially face ostracization from the group and could have disastrous results for the survival of the murderer.

In modern society, there is no country where murder can legally take place. For example, the very definition of murder is the *unlawful* killing of another. The term "lawful murder" can be considered an oxymoron; the very meaning contradicts itself. Further, all modern judicial systems consider crimes that involve murder to be very serious, and these crimes often carry serious punishments. When it comes to murders within the family unit, studies conducted within the realm of evolutionary psychology seem to help offer an explanation. A study conducted by

Daly and Wilson reported that “Most ‘family’ homicides are spousal homicides, fueled by male sexual proprietariness. In the case of parent-offspring conflict, an evolutionary model predicts variations in the risk of violence as a function of the ages, sexes, and other characteristics of protagonists, and these predictions are upheld in tests with data on infanticides, parricides, and filicides” (Daly and Wilson 1988). This study helps shed light into some potentially relevant motives regarding murder in ancestral times.

Conclusion

In conclusion, the act of murder is as timeless as life itself. Humans are not the only species that is known to commit murder, as intentional killings have been documented within certain ape populations. Further research into the motivations of murder will hopefully shed additional light into this topic.

Definition

Music is an art form and cultural activity whose language is organized in time with logic and sensitivity the sounds and silences. Originally, the word derives from Greek *mousiké [technē]* that means the “technique of Muses.” It combines harmony, melody, rhythm, pitch, meter, timbre, etc. to create psychoanomic states with hormones, steroids, and other metabolic endogen compounds contributing to those effects.

Introduction

Musical stimuli in humans have been proved to be related with emotional areas of the brain such as insula, cingulate cortex, hypothalamus, hippocampus, amygdala, and prefrontal cortex (Boso et al. 2006). Probably nobody would disagree in the asseveration music has an effect over our moods, reducing stress, increasing well-being, improving social boundaries, and even over our motivation. When people needs to have energy to work, to drive, to train, to have fun, etc. music is a recurrent and common resource for natural energizing. Music has an effect on our metabolism and bodies which might guide toward those desirable mental states; in a human study, it was found an increase in saliva of 26 healthy young men, for their secretions of oxytocin release (positive social ties hormone) and a decrease for their cortisol release (stress, anxiety, and depression hormone) after exposure to music (Further details in chapter ► [“Anxiety”](#) and ► [“Depression”](#) of this encyclopedia.). Moreover, those cortisol levels positively correlated with the arousal level after listening several piano music pieces composed by Chopin (Ooishi et al. 2017). Nitric oxide (NO), endorphins, endocannabinoids, and dopamine have been suggested to play a role being released to the bloodstream with the musical experience (Boso et al. 2006).

Music also informs about our personal stories or cultural backgrounds, since we use to like what we have most listened, whether chosen or not. Or because inside a certain cultural or historical context, a virtuous musicians pursuits to do better than the most of the other people inside a group (Sloboda 1994). For instance, the question *“What kind of music do you like?”* is a very typical question to know someone better, at the beginning of any friendship, next to the question *“Do you come here very often?”* Not only a bidirectional connection to our mood or mental states but also what sort of music we rather, might be giving also information about ourselves, which in turn, enlightens about our personalities, specific personal characteristics, or cognitive styles (Greenberg et al. 2015). Two different forms of well-defined personalities were given

depending on our most pronounced musical preferences: type E (low rhythm, melodic songs, soft arousal) and type S (animated, intense, tension, or thrilling music). For this well-documented classification, they used NEO-PI-R tests results beside the participants physiological reactions to their preferential variety of musical stimuli (Greenberg et al. 2015).

Wherever they come from, most songs and music in general are written in a mathematical language, following cycles, loops, logic sequences (waves, mirror, dialogues) using several parameters well understood by anyone, rhythm, tonalities, accelerations, intensities, etc. The nature of learning to play music will depend on practicing, specifically how much and what is done during that practicing (Sloboda 1994), because playing music combines motor skills besides a high cognitive learning. And it magically happens, that even the simplest tune with the simplest notes in some order sequence might have a sense and good meaning for all of us in many different cultures, languages, latitudes (i.e., Fur Frère Jacques) (Sloboda 1994). Music gives comfort to our brains. However, beyond a doubt understanding music is not a matter of perceiving single stimuli into patters and relating those patterns one another, as Gestalt Psychologist has proved. The same musical stimuli may have many different meanings (Furtger detausk Meyer 1994) (Further details, see chapter ► [“Evolutionary Musicology”](#) in this encyclopedia.).

Although, on the other hand, there are some sort of music with dark legends or “diabolic attributes” associated. These types of music have been affiliated with delinquent manners, such as violence or aggressive actions, drugs abuse, or promiscuous sex. A recent study proved listening to this type of music might have an effect on risk-taking likelihood behavior, although those risks did not happen in areas of health or safety (Enström and Schmaltz 2017). It has been proved that heavy metal might cause different autonomic responses because it’s loud and intensity heavy change heart rhythm rate, respiration rate, and finger temperature in a group of young women (Cheng and Tsai 2016). The soft and most relaxing musical passages induced stronger parasympathetic activity compared with the loud

passages (Cheng and Tsai 2016). Specially for the high intensity or loudness, dancing heavy metal moving head with long hair might cause injuries to the neck or vertebrates. It has been calculated the injury is depending on the constant gravity, the acceleration of movement, and the velocity of the head movements relative to T1 vertebra and the center of balance of the head (Patton and McIntosh 2008). Heavy metal songs have an average tempo of 146 beats per minute and that tempo in head banging of a range of motion of the head over than 45 might predict to cause at least headaches and dizziness (Patton and McIntosh 2008). One clinical teenager case of vertebral artery aneurism after head banging by heavy metal young drummer was described (Egnor et al. 1991).

But not only heavy metal has been considered as diabolic, also pagan music such as folkloric songs or music full of intensity and energy, such as Rock and Roll or Jazz had negative moral values at some point or historical moment. In a study performed over professional women musicians (pianists), it was defined the positive concepts for music in terms of morality and logic are represented by regularity and prediction in musical structures, without much dissonances, roughness, and the narrower pitch range, while the opposite is true for the negativity for music (Mesz et al. 2015).

Castrati: male sopranos in opera

The ancient concept of castrato was given by Jacques Rousseau in 1778, as “*a musician (singer) who, in infancy, has been deprived of his genital organs in order to preserve his high voice*” (Sundberg et al. 2007). Castrati singers were able to produce a distinctive resonance as well as the high pitch, which cannot be matched even by great non mutilated male singers of today (King et al. 2001). They used to be taller than their noncastrated fellows because of the growth plates did not close and growth hormone continued its release. Their facial features used to be feminine (King et al. 2001), consequently they were playing and singing both roles male and female in opera for more than 200 years (1600–1850) (Melicow 1983; Zegers 2009), having their own

specific compositions such as George Frederic Handel did (1685–1759) with opera *Rinaldo* fitting their particular voice range. Castrati had developed the chest of a man, but their vocal cords were like those of a woman having their voices an incredible power, resonance, and control of breathing (Melicow 1983). The ranges of their voices were sometimes of four octaves, and they were carefully educated in vocal art and music (Sundberg et al. 2007). Sometimes they presented obesity, gynecomastia, and steatopygia, but they preserved their heterosexual desires, despite of their sterility (Melicow 1983). The voice of the last castrato, Alessandro Moreschi, can be listened nowadays to gramophone recordings from the beginning of past century. Each castrati voice had their particular color and characteristics; however, they all used to be described as sweet, soft, and ingratiating, or hard, brilliant, and penetrating (Sundberg et al. 2007).

In a study performed over Farinelli's skeleton (Andria, 1705 – Bologna, 1782), who was an Italian singer castrato very famous, it was observed his bones had interesting characteristics probably related to the effects of castration before puberty. Farinelli's real name was Carlo Maria Michelangelo Nicola Broschi. Farinelli presented long limb-bones, periphyseal lines and osteoporosis, bone mineral density, together with skull frontal bone affected by severe hyperostosis frontalis interna (HFI) (Belcastro et al. 2011). It is known the production of interleukin-6 (IL-6) by osteoblast is inhibited by estrogen and androgen, being the bone loss increased by ten times after menopause in woman or following castration in men mainly because of overproduction of IL-6 (Zanatta et al. 2016). Actually, Farinelli's HFI was classified as the most severe grade (type D), because the bone thickness ranges was from 9 mm at the sagittal sulcus to 21 mm at the maximally thickened area. Farinelli was a very good companion for the Spanish King Philip V who suffered for melancholia. He used to listen to Farinelli and his voice helped the King to improve his mood (Melicow 1983).

In general population, a study on 1532 autopsies during 4 years searching for HFI found 13 cases with this disease, 12 women and 1 man

(an incidence of 0.8%). It is characterized by thickening of the frontal skull bone associated with roughness of the endocranial surface in a graduation from type A (less severe) to type D (more severe) (Devriendt et al. 2005). Some behavioral disorders and hormonal diseases have been described with this pathology such as virilism, hirsutism, fatigue, somnolence, obesity, irritability, aggressive behavior, vertigo, polydipsia, polyuria, loss of sense of smell, Pick's disease, Alzheimer disease, cerebral atherosclerosis, dementia praecox, etc. (Devriendt et al. 2005). Many of them are related with the hypothalamus and its homeostatic metabolisms.

The preauricular sulcus was found to be different in castrati too. Farinelli had an absence of preauricular sulcus in his left hip bone, in the male common value range for this parameter (Belcastro et al. 2011). In nonmutilated people, 500 *ossa coxae* were analyzed and it was found a sex difference in this bone morphology, being in males more likely to display a short and narrow sulcus in bone, while in female, probably because of their different pelvic shapes and bells, their sulcus shape was wider and longer (Karsten 2018). Only 10.04% of females analyzed had nonpreauricular sulcus or very narrow.

Farinelli's voice could span over three octaves and his thoracic development allowed him to hold a note without interruptions for breathing during a whole minute. Unfortunately, for his honor and memory, his bones were not well preserved since they were located at the feet of his great-niece grave (Belcastro et al. 2011). He was described as having an inclination to melancholy that got worse with advancing age, perhaps because of T deficiency, having his androgen receptors functional. Perhaps some metabolic loop could have been modified and having some other indirect effect over corticosterone because of a different metabolic instructions for homeostasis balance. On the other hand, castrati were relieved from some testosterone effects over the metabolism, besides the lowering of voice, such as alopecia, thickening of the dermis, development of acne, and formation of male pelvis (Zegers 2009).

Another castrato singer gonadecomized before 12 years old was Gaspare Pacchierotti

(1740–1821) and his skeleton was also studied. He was posterior to Farinelli and also presented in his skeleton some androgen deprivation effects. The posture for singing requires an elongated neck compared with the shoulders, to allow air and sounds passing, specially for acute sounds such as erosion of cervical vertebrae. In Pacchierotti skeleton was found an insertion of respiratory muscles and muscles of the arms, and osteoporosis (Zanatta et al. 2016). The cause of his death was dropsy, being related the liquid metabolism with vasopressin and other hormones in the body, including testosterone. His teeth were white and a dental health preserved. However, an advanced dental erosion, probably due to bruxism, was described that might have happened because of a persistent distress (Zanatta et al. 2016) or for the physical pain caused by muscular atrophies.

As mentioned previously referring to heavy metal, bodily musical performances might induce injuries to the body. Musical ecstasy itself might drive into impossible body postures for long time without perceiving pain, perhaps because of endorphins or other hormones released. Body movements of wrist, torso, and head made by musicians while playing use to be related to specific structural musical features (Sloboda 1994).

Another well-known castrato singer was Domenico Caffarelli (1710–1783). He was a rival of Farinelli but with an unpleasant personality; he refused to sing for Royalty and he returned gifts from Royalty (Melicow 1983). Caffarelli's real name was Gaetano Majorano, but he adopted his artistic name the same of his "benefactor" who castrated him (Melicow 1983). For the surgical intervention of gonadectomy, narcotics such as opium were sometimes used for neutered kids, and the majority of victims died as result (Zegers 2009). A heavy psychological tax after this irrevocable intervention should still be considered for fully understanding of the betrayal happened to them who did not chose to lose their chances for procreation (Zegers 2009). However, a psychological defense mechanism to deal with this injustice might be the arrogance that is a common characteristic for some castrati singers; they used to believe their voices were more than divine, beyond god design. For instance, the castrati Giovanni Battista

Velluti (1781–1861) once quoted “*My throat is worth as much as a queen!*” (Melicow 1983).

However, on the other hand, testosterone might also have an effect over voice on adult singers. A case of a 22 years old man singer with hypogonadism (only one testicle and hidied in the inguinal canal) who was treated with adult exogenous testosterone was described. While hormonal treatment was supplied, his voice control for singing was elusive, a decreased pitch and an alteration of quality for his voice control happened. After hormonal treatment was over, his final voice range changed to a different level from a tenor to a baritone (King et al. 2001).

Many studies have been done trying to understand how these steroids might affect art, quality of sounds, or even long lasting of singer expectancies. A correlational analysis were done just comparing ages of deacease for singers of both genders. They compared mean ages of death for singer women and man in a particular population studied (from years 1900 to 1995, 292 female singers and 505 male singers) and they concluded that androgens might have a protective effect in woman lives (Nieschlag 2003).

Hormones in Musicians

A different gender expression of roles has been described for professional musicians with musical talents; male musicians show a higher rate of female-typical gender role behavior while the opposite (male-typical gender role behavior) is true for female musicians, compared to nonmusicians people (Hassler 1991). As a hypothesis to this fact is an excess of testosterone levels during development embrionary organizational period inside the womb, from weeks 20 of gestation on, has been discussed. Also a different brain hemispheres balance might happened for this particular early hormonal change which leads to a different distribution of tasks among brain hemispheres (Hassler 1991). Men, but not women musicians, have been described more often to be non-right-handed than their fellows nonmusicians (Hassler 1991).

Measuring the digit ratio and musical aptitude some interesting results were found, suggesting

the testosterone levels are related to musical talent but only in female groups (Borniger et al. 2013). Spearman correlation coefficient was found in between those with greater musical ability and their lower digit ratio, supposedly related to higher prenatal androgen exposure. Their musical talented and professionalism in music were measured with the test Advanced Measures of Music Audition (AMMA). A lack of differences in AMMA total raw scores in relation to testosterone was found, but testosterone exposure might facilitate the acquisition of musical aptitude, in terms of competitive skills for music inside a such as an orchestra (Borniger et al. 2013) (Further details, see chapther ► “[Resource Competition](#)” and ► [Status Competition](#) in this encyclopedia). Concerning to this difference in testosterone levels, some autoimmune disorders, related to the immune system and the complex interaction of testosterone with other hormones and neurotransmitters, have been described more often in musicians than in nonmusicians (Hassler 1991).

It has been proved that in humans and rodents, steroid hormones confer some sort of neuronal plasticity but also they have effects over the immune system or mood states. Several empirical evidences would make plausible to assert that music confers neuronal plasticity by affecting steroid hormones and alleviating or relieving stress (Fukui and Toyoshima 2014). Moderately higher levels of testosterone in women (positive correlation) and lower levels of testosterone in men (negative correlation) compared to their basal nonmusicians groups was found, indicating an effect of T in better talents for music. Moreover, a tendency but not significant to a positive relationship between a polymorphism (repeat length) in the androgen receptor (AR) and T levels was described (Fukui and Toyoshima 2014).

Studies with Rodents

A study on rats proved that exposing animals to music during 21 consecutive days significantly enhanced neurotrophins brain-derived neurotropic factor (BDNF) and reducing nerve growth factor (NGF) in rats hypothalamus (Angelucci et al.

2007). Music presented were recordings with no voice added, such as a compilation of New Age songs (Enya).

In a different study, classical music (Mozart) was exposed to Wistar rats and after that, they found changes in dopamine levels (DA), prolactin (PRL), and corticosterone happened in different brain areas (striatal nucleus-SN, prefrontal cortex-PFC, and mesencephalon-MS) (Tasset et al. 2012). Haloperidol is known to block dopamine receptors in the adenohypophysis, having an effect over the PRL releasing inhibiting its secretion. Music exposure was able to prevent the drop in DA prompted by haloperidol administration, specifically marked at the PFC and MS, having a lesser effect over the SN (Tasset et al. 2012).

Conclusion

Music is an ephemeral creation of art that exists in all the cultures in the world. They do happen in our brain while playing and just some time after played, producing emotions and metabolism reactions (For further details see chapter ► “Emotions” of this encyclopedia). Hormones have very relevant aspects for music production such as voice qualities and range of singers. Past century, castrati were prepuberal gonadectomized and their entire metabolism suffered from activational and organizational changes for a forced to a rebalanced not programmed. Even the skeleton, bones, and skulls might have morphological differences after early castration. On the other hand, testosterone has also an effect over good musicians and excellent musical performances. Another molecules related to emotions are involved in musical art, such as NO, endorphins, endocannabinoids, and dopamine; they are released to our bloodstream while listening music as the artistic creation which remains in memory.

Music as Auditory Cheesecake

Hadas Shintel

Department of Psychology, Center for Academic Studies, Or Yehuda, Israel

Synonyms

Music as by-product; Non-adaptationist view of music

Definition

As per Pinker's hypothesis, music is not evolutionary adaptive, but rather is a by-product of other evolutionarily evolved traits, and one that

serves no biological function. Pinker suggests that music is an “auditory cheesecake.” Cheesecake fulfills our evolved desire for fat and sugar, but the desire for cheesecake did not evolve and is merely a by-product, pleasurable but biologically useless. Similarly, Pinker regards music as a highly pleasurable by-product of the evolution of other mental faculties, primarily language.

Introduction

In *How the Mind Works* (Pinker, 1997), Steven Pinker offers an account of how the major faculties of mind were designed by natural selection. However, not all mental faculties have evolved through natural selection. Music, for Pinker, represents a clear example of a nonadaptive “pure pleasure technology, a cocktail of recreational drugs that we ingest through the ear to stimulate a mass of pleasure circuits at once” (p. 528), an auditory cheesecake. Although it may contribute to the well-being of the individual, music is biologically useless: “It shows no signs of design for attaining a goal such as long life, grandchildren, or accurate perception and prediction of the world. Compared with language, vision, social reasoning, and physical know-how, music could vanish from our species and the rest of our lifestyle would be virtually unchanged” (p. 528).

Instead of being an adaptation that was the direct target of natural selection, Pinker sees music as capitalizing on preexisting adaptive mental faculties: (1) language, in particular prosody, which involves the analysis of intonation contours, metrical structure, and hierarchical grouping of phrases; (2) auditory scene analysis, which draws on attention to harmonic relations for the process of segregating components from different sources and integrating components originating from the same source; (3) emotional calls that use acoustic signals associated with specific emotions and thus serve a communicative function; (4) habitat selection which involves attention to evocative environmental sounds; (5) motor control, involved in the rhythmic movement to music. All of these are fitness enhancing and are rewarded by a sensation of pleasure emitted by the pleasure centers of the brain. Music, as a pleasure

technology, pushes all the right buttons, without enhancing fitness itself.

The Pleasure of Music

Before turning to the issue of the biological function of music and its evolutionary roots, it is important not to overlook the emphasis, embedded in Pinker's cheesecake hypothesis, on music's unique ability to evoke pleasure. Whether or not the pleasure derived from music is an upshot of music's ability to stimulate the mental faculties suggested by Pinker as providing the mental machinery for music, research provided support for the notion that music is experienced as a highly potent emotion-evoking pleasure-inducing stimulus. Furthermore, the rewarding effect of music appears to be mediated by the same reward brain circuits as the effect of biologically relevant rewarding stimuli; for example, research has implicated the mesolimbic dopaminergic reward system as involved in musical pleasure (see Chanda and Levitin 2013).

Music: Adaptation or Cultural Creation?

Pinker's position lies at one extreme of the debate regarding music's adaptive function. For Pinker, music is not an adaptation, produced through the process of natural selection for its current function, but rather a spandrel, a by-product of other adaptive mental functions. But moreover, even music's current use is biologically functionless (as suggested by the cheesecake analogy). A less extreme position is Patel's theory that sees music as a human invention, albeit a biologically powerful one (Patel 2010). Like Pinker, Patel argues that music is rooted in non-musical functions, and thus a parsimonious explanation would not assume it has been shaped by natural selection. However, Patel sees music as a "transformative technology of the mind" in the sense that musical engagement and training can have beneficial enduring effects on other brain functions, such as language, attention, and executive function, thereby transforming the biological functions

underlying it. These effects span individual time-scales, as music needs to be learned anew by each generation and does not involve any further modification of the human brain specifically for musicality.

At the other extreme of the debate lie positions that deem music, or musicality, an adaptation. Two kinds of arguments have been advanced in support of music being an adaptation. The first kind of arguments concerns its adaptive function; we will review these arguments in the next section. The second kind focuses on characteristics of music that make it a likely candidate for an evolutionary explanation. For example, music needs to have been around long enough to be shaped by natural selection. Although it is not known at what point in history music came into existence, archeological evidence points to the existence of flutes approximately 40,000 years ago (Conard et al. 2009), suggesting an even older musical tradition. Music is universal and observed across cultures. Furthermore, music needs to be innately constrained to be the target of natural selection. Evidence suggests that at least some aspects of music are indeed innately constrained; for example, even young infants show sensitivity to musical structure, such as melodic pitch contours (see McDermott and Hauser 2005 for a review). However, it is not clear whether music satisfies the criterion of domain-specificity. As suggested by Pinker, sensitivity to pitch can result from adaptations for language and auditory scene analysis (see McDermott and Hauser 2005). The lack of domain-specificity suggests that music may be an exaptation (Gould 1991), not produced by natural selection for its current function but rather coopting traits evolved for other functions. Unlike Pinker's cheesecake idea, the idea of music as an exaptation leaves open the possibility that it does serve a biological function, albeit a novel one that did not result through natural selection.

The Adaptive Value of Music

Different theories have suggested several ways in which music can be fitness-enhancing. One

possibility, suggested already by Darwin in *The Descent of Man*, is that music evolved through sexual selection and functions to attract sexual mates. Music, and the dance that accompanies it, has features that may act as indicators of fitness, coordination, strength, and health (Miller 2000). On the other hand, in contrast to other species in which song is performed by males, mainly during mating season, music is performed by both males and females in a wide range of contexts. Currently, empirical evidence for the function of music in sexual selection is lacking.

Another possibility is that the function of music lies in its role in childcare. Cross-culturally, caregivers use lullabies and play songs to soothe infants and regulate their arousal; such expressive vocal communication also strengthens mother–infant affiliative bonding. Thus, songs and rhythmic vocalizations may have adaptive value for the infant. Infant Directed Speech (“motherese”), with its exaggerated intonation contours and stress patterns, may fill a similar function (Trehub, 2003).

Another potential function of music is in increasing group cohesion. Dunbar (2004) proposed that music functioned as vocal grooming, replacing physical grooming when group size increased too much to allow for physical grooming. According to Dunbar, vocal grooming mimics the endorphin-releasing effects of social grooming, thereby creating feelings of warmth and trust that contribute to social bonding. Music may also promote rhythmic synchronization and coordination at the group level, thereby contributing to group identity and cooperation (Brown 2000).

Conclusion

The idea of music as an auditory cheesecake was suggested by Pinker as a counterexample to his adaptationist account of the major faculties of mind. Pinker suggests that features we see as beneficial or adaptive, in the colloquial sense of the word of contributing to better adjustment, may not be adaptive in the biological sense, and were not the target of natural selection. Music is a

by-product of the evolution of other mental functions, pleasure-inducing, but nonetheless biologically functionless.

Although Pinker’s point regarding the pleasure-inducing effects of music is uncontested, his view regarding the evolutionary roots of music and its function has been disputed by theories that suggested various potential adaptive functions of music. In effect, Pinker’s controversial suggestion has sparked a renewed interest in the evolution of music. However, much of the debate remains speculative and is in need of clear empirically testable hypotheses and empirical evidence.

Musical Protolanguage

Hadas Shintel
Department of Psychology, Center for Academic
Studies, Or Yehuda, Israel

Synonyms

Evolutionary precursor to language and music;
Prosodic protolanguage

Definition

Musical protolanguage refers to a hypothetical intermediary stage in the evolution of language, intervening between a non-linguistic stage and the possession of true language. Musical protolanguage at that stage consisted of non-referential song and served as the common ancestor of both language and music.

Introduction

Theories of language evolution often invoke a hypothetical protolanguage stage, a stage that

serves as a precursor and as a scaffold for the evolution of modern language. The idea of such an intervening stage, and the notion that this protolanguage was akin to song and is the common ancestor of both music and language, can be traced back to Darwin. In *The Descent of Man and Selection in Relation to Sex* (Darwin, 1875), Darwin considers the evolution of language and claims that “[. . .] primeval man, or rather some early progenitor of man, probably first used his voice in producing true musical cadences, that is in singing, as do some of the gibbon-apes at the present day; and we may conclude from a widely-spread analogy, that this power would have been especially exerted during the courtship of the sexes,—would have expressed various emotions, such as love, jealousy, triumph,—and would have served as a challenge to rivals” (p. 87). Drawing on an analogy to birdsong, which like language needs to be learned and is practiced by the young members of the species, Darwin argues that human vocal imitation was driven by sexual selection. He then traces the emergence of meaningful words to the vocal imitation of natural sounds, other animal vocalizations, or man’s own instinctive vocalizations: “It is, therefore, probable that the imitation of musical cries by articulate sounds may have given rise to words expressive of various complex emotions” (ibid.).

Fitch (2010), in a modern framing of Darwin’s theory, says “prosodic protolanguage was a system with phonological generativity, using a small set of elements to build hierarchical structures. These structures were vocally generated, voluntarily controlled, and learned, sharing core aspects of speech and song” (p. 476). Fitch argues that the musical protolanguage model can explain the design features shared by language and music, such as the use of a vocal/auditory channel, discreteness, productivity, and cultural transmission (for a complete list, see Fitch 2010, p. 469). He further argues that comparative data documenting the evolution of vocal learning in several non-bird species, as well as neuroscientific data showing an overlap in the mechanisms underlying the processing of music and language, provide support for Darwin’s musical protolanguage hypothesis. For example, people with congenital amusia, who are impaired in their ability to process music, also

exhibit reduced ability to process emotional speech prosody, suggesting a common acoustic code (Thompson et al. 2012). It should be noted though that overlap in processing mechanisms, while consistent with Darwin's hypothesis, can be explained by seeing music as dependent on processes that evolved for language or vice versa, and does not necessarily imply a common evolutionary ancestor.

In Fitch's terms, musical protolanguage can be described as bare phonology, that is a system with generative phonology such that units can be hierarchically combined but devoid of semantics, with some elements of syntax (units that can be combined and hierarchically arranged in phrases). The main problem for the musical protolanguage model is explaining how such "bare phonology" evolved into a meaningful system that combines phonology and semantics.

Modern Versions of the Musical Protolanguage Hypothesis

The idea of a musical protolanguage, a common precursor of language and music, has been revived by modern scholars. Brown's (2000) *musilanguage* model provides one such example. Brown traces the emergence of musilanguage to primate emotive referential vocalizations – emotive calls elicited in response to a specific class of objects, for example, the alarm calls of vervet monkeys. According to Brown (2000), in the first protolanguage stage, musilanguage involved discrete-level pitches and the use of pitch for conveying semantic meaning, similar to the way lexical tones can differentiate meanings in tonal languages. The second stage involved combinatorial formation of phrases and expressive phrasing. However, the idea of discrete-level pitches, found in music but not in speech, was later (Brown 2017) replaced with the idea of an imprecise relative pitch system (high vs. low). Another way tones can potentially convey meaning is by capitalizing on cross-modal mappings between pitch and non-auditory properties such as size, brightness, and position (Brown 2017). Indeed, research has shown that such cross-modal mappings underlie some sound symbolic words and can also be

exploited for conveying meaning through prosody (see Perniss et al. 2010).

Another model is Mithen's *Hmmmm* model (Mithen, 2005), termed so because it sees protolanguage as **h**olistic, **m**anipulative (used for manipulation of emotion and behavior rather than for reference), **m**ulti-modal (using movement, such as gesture and dance, as well as sound), **m**usical, and **m**imetic. Unlike the musilanguage in Brown's model that consists of discrete-level tones, in Mithen's *Hmmmm* model, utterances are holistic, rather than combined out of elements that can be recombined. The evolution of modern language then involved the segmentation of *Hmmmm*.

Non-music Models of Protolanguage

Other theories accepted the idea of a protolanguage stage but rejected the notion that this protolanguage was musical in nature (for an extensive review of protolanguage models, see Fitch 2010). One such model is Bickerton's (1990) lexical protolanguage model, according to which protolanguage is a propositionally meaningful system, consisting of a lexicon of meaningful words, but no syntax. Bickerton sees language as primarily representational, rather than communicative. He thus rejects the continuity between language and animal communication systems, focusing instead on the conceptual system as the precursor underlying protolanguage.

Another model is the gestural protolanguage model (see Arbib 2005; Corballis 2002). Although speech can iconically represent meaning through speech sounds or prosody (Perniss et al. 2010), gesture allows far more possibilities for iconicity. Gestural protolanguage is propositionally meaningful, thereby avoiding the difficulty that musical protolanguage faces in explaining the emergence of semantics. The modern discovery of the mirror neuron system suggests a mechanism that enables parity in gesture understanding, which may serve as a precursor to the complex imitation observed in humans and to protolanguage (Arbib 2005). The problem facing gestural theories is explaining the transition from gesture and the manual modality to speech.

Conclusion

The idea of a musical protolanguage, that is a common precursor to both music and language, was originally suggested by Darwin in *The descent of men* and has since been revived and reformulated by contemporary theorists. Although all models share this idea of a common ancestor, the presumed characteristics of the musical protolanguage differ between theories (e.g., synthetic vs. holistic). New evidence for shared brain mechanisms underlying music and language has been interpreted as supporting theories that posit a common evolutionary origin and led to renewed interest in Darwin's musical protolanguage model. The transition from musical protolanguage to meaningful speech remains a challenge for the musical protolanguage hypothesis.

Definition

Mutation is defined as a permanent change occurring in the DNA, i.e., nucleotide sequence of a gene or chromosome.

Introduction

Gene is the functional unit of DNA. The characteristic of an individual is determined by its genetic pool. The genes are transferred to the organism from the parental genetic pool through complex process of reproduction. Mutation is a process of alteration of nucleotide sequence within a gene. Altered gene sequence in DNA ultimately leads to alteration in all copies of proteins encoded by that DNA. The alterations in proteins can lead to change in development and functioning of an organism (Lodish et al. 2000).

The genetic configurations keep on changing due to mutational process (Moorjani et al. 2016). The gene-environmental interaction is involved to

a larger extent in this complex process. By this evolutionary process, the organism attempts to meet the needs for survival, i.e., mutation keeps an organism evolving. However, mutation also attributes to the extinction of species.

Mutation rate is defined as “the probability that a change in genetic information is passed to the next generation” (Sanjuán and Domingo-Calap 2016). The rate of mutation reflects the rate of evolution (Peck and Lauring 2018). The rate (speed) at which the mutation occurs represents the speed at which genetic diversity occurs in a given population. In humans, the most frequently mutated genes are those genes that are associated with various cancers (oncogenes) (Gorlov et al. 2018). Mutability of a gene (i.e., ability of the gene to mutate) depends on several characteristics of the gene. The genes that have higher level of expression, slowly replicating in nature and higher chromatin accessibility, are more associated with somatic mutations (Gorlov et al. 2018; Park et al. 2012). Information is carried by the genes. Genes determine the characteristics inherited from the parents. Germline mutation arrests the passage of information or transmits erroneous information (characteristics) to the next generation (Sally 2016).

Types of Mutation and Their Health Implications

Mutation of various types has been implicated in different health conditions. Mutation that involves germ cells (sperm, ovum) is known as germline mutation. Mutations involving non-germline cells are known as somatic mutations (Loewe 2008). Germline mutations are transmitted to progeny and lead to inherited disorders. Somatic mutations, on the other hand, are not transmitted to the progeny. Somatic mutations are mostly manifested as cancers (Kumar et al. 2017). Mutations in specific genes produce alteration in myeloproliferation in an unregulated manner resulting in hematological malignancies (Ortmann et al. 2015). Genetic mutation too attributes to the development of prion diseases like Creutzfeldt-Jakob disease (Gao et al. 2019).

Alleles are different forms of a gene (e.g., normal and mutant). In diploid organisms, genes occur in pairs. If mutant phenotype appears only when both alleles are mutated (i.e., individual is homozygous for the mutant allele), it is termed as recessive mutation. If mutant phenotype can appear even with one mutated allele (i.e., individual is heterozygous for the mutant allele), it is termed as dominant mutation (Lodish et al. 2000). Recessive mutations mostly lead to a loss of function, whereas dominant mutations lead to gain of function. Genetic disorders thus can be dominant and recessive depending on their pattern of inheritance. Autosomal disorders (due to mutation in autosomes) can be dominant (e.g., Huntington's disease, Marfan syndrome, type 1 neurofibromatosis) and recessive (e.g., sickle cell anemia, thalassemia, cystic fibrosis, phenylketonuria, glycogen storage diseases). X-linked disorders account for almost all sex-linked disorders (mutations occurring in X and Y chromosomes) and are mostly recessive (e.g., hemophilia, Duchenne muscular dystrophy).

Alteration in a single base pair is called a point mutation (Lodish et al. 2000; Loewe 2008). Such mutations lead to either the production of a different protein (missense mutation) or the premature termination of a protein (nonsense mutation). Sickle cell anemia is autosomal recessive disorder due to missense point mutation that causes GUG codon (coding for valine) to replace normal GAG codon (coding for glutamic acid). Alteration in β chain of hemoglobin (Hb) caused due to this mutation causes decrease in oxygen-carrying capacity of Hb and sickling. Nonsense mutations lead to degradation of RNA. Frameshift mutation is a type of mutation that occurs when there is insertion or deletion of one or two base pairs, leading to altered reading frame of the DNA strand. Trinucleotide repeat sequences in an unregulated fashion occur due to certain dynamic mutation processes (Pearson et al. 2005). Fragile X syndrome characterized by mental retardation is an example of trinucleotide repeat where there are tandem repeats of CGG codon in *FMR1* gene. Mutations that result in expanded repeat sequences of trinucleotides result in development of several neurological as well as neuropsychiatric disorders (Pearson et al. 2005).

Mutation in Nonhumans

The process of mutation occurs in all living organisms. Mutation in microorganisms results in their evolution (Peck and Lauring 2018). Mutations can be spontaneous or can be induced by mutagens like UV radiations and alkylating agents (Watford and Warrington 2019). Mutation can alter the pathogenic characteristics of a microbe (Hershberg 2015; Sanjuán and Domingo-Calap 2016). Mutation may accentuate or attenuate the virulence of pathogenic microorganisms. Oral polio (Sabin) vaccine, for example, is produced by attenuating polio virus. These vaccine strains of poliovirus were developed by serial culture in monkey kidney cells. Mutation and selection produced this strain of poliovirus which retains its immunogenicity but has lost its pathogenicity (Fleischmann 1996). Different microorganisms have different rates of mutation. The rate of mutation in RNA viruses is higher than that of DNA viruses. Human immunodeficiency virus (HIV), for example, is a highly mutable virus. Sequential isolates of HIV from the same person can show antigenic variation. Similarly, faster mutation is reported among viruses with single-stranded nucleic acid than viruses with double-stranded nucleic acid (Sanjuán and Domingo-Calap 2016). Viruses with segmented nucleic acid (e.g., influenza virus) also show higher rate of mutation than those with unsegmented nucleic acid. Mutations in HIV lead to development of drug resistance. Drug resistance in bacteria like *Mycobacterium tuberculosis* and *Helicobacter pylori* is mainly due to mutations. Mutation attributes to the continued evolution of acquired resistance genes too, like TEM family of beta-lactamases which are generally transmitted from one bacterium to another by horizontal gene transfer methods (e.g., conjugation) (Woodford and Ellington 2007).

Mutations: From the Perspective of Evolution

In the process of evolution, mutation is always a possibility as well as probability, as gene-environmental interaction is happening continuously in an intricate manner. The genetic

variations seen among organisms during the developmental process are the result of mutation (Lynch et al. 2016). However, the probability of mutations varies according to their nature. Some forms of mutations are more likely to happen, whereas certain others are rare to happen (García and Traulsen 2012). Epigenetic mutations that result from gene-environmental interactions have beneficial effects. They help the organism in adapting with the changing environment. Successful adaptation is highly essential for survival. However, certain epigenetic mutations slow the adaptation process and may stand as a hindrance too (Kronholm and Collins 2016). In the process of evolution, nature selects organisms that are adaptable and fit by shaping their phenotype. The role of mutations in this process of natural selection is still debatable (Svensson and Berger 2019; Uller et al. 2018).

Mutation rate is important from the evolutionary point of view. Mutation rates vary among different species of organisms as well as with same species of organisms. It has been seen that the mutation rates humans have are lower than gorillas and chimpanzee. Similarly, among human race, mutation rate is found to be higher within certain DNA regions of Europeans than Africans and East Asians, as found in some research (Harris and Pritchard 2017).

Mutated genes code for specific proteins that subserve a particular function. The proteins coded by the mutated genes ensemble various permutations and combinations to a final configuration, which is unpredictable. So, as per the existing knowledge, prediction of evolution remains uncertain (Sailer and Harms 2017).

Conclusion

The phenotypic variations among living organisms trace back to mutation. Many illnesses and their risk factors can be understood through the knowledge of mutation. Extensive research for in-depth understanding about mutation and its aftereffects may enable us in understanding the evolutionary process and even may guide us in predicting evolution.

Mutation Accumulation Theory

Michael A. Woodley of Menie

Center Leo Apostel for Interdisciplinary Studies,
Vrije Universiteit Brussel, Brussels, Belgium
Unz Foundation, Palo Alto, CA, USA

Definition

Mutation accumulation theory describes two interconnected bodies of theory: (i) *Germ-line mutation accumulation theory* attempts to understand both the consequences of and the processes by which a population's *load* or *burden* of

spontaneously occurring germ-line mutations increases in the absence of purifying selection, which results from the fitness diminishing effects of these mutations, and (ii) *Somatic mutation accumulation theory* encompasses the related phenomenon of cell lineages within multicellular organisms accumulating mutations as a result of failures of DNA repair in the course of mitotic cell division. These phenomena have important implications for understanding the origin of variance and covariance among fitness salient traits and the maintenance of population viability in the case of germ-line mutation accumulation and senescence and oncogenesis (the mechanisms by which cancer-causing neoplasms form) in the case of somatic mutation accumulation.

Introduction

This entry will start by introducing relevant background concepts, such as the nature of purifying selection, the relationship between fitness, pleiotropy and trait variance, and the sources and rates of new germ-line and somatic mutations. As the target audience for this entry is evolutionary psychologists, whose principal organismal focus is *Homo sapiens*, the entry will then summarize the human mutation load paradox, its resolution, and potential manifestations of ongoing mutation accumulation in human populations. Experimental evidence of the fitness reducing consequences of accumulating germ-line mutations in relation to work on nonhuman eukaryotic taxa will also be discussed. Finally, the possibility that there exists a group-selection level manifestation of purifying selection will be considered.

Review

Purifying Selection

Purifying selection describes the processes by which mutations are eliminated from a population as a consequence of their deleterious effects on fitness. This can occur via *natural selection* under conditions where the carriers of deleterious mutations exhibit suboptimal levels of traits critical for survival, such as in the case of defenses against

predation and disease, or where mutations that interfere with critical biochemical processes lead to prereproductive organismal death at some point in the lifecycle or sterility. A parallel process of *somatic selection* operates at the cellular level, whereby newly acquired deleterious mutations trigger immunological policing responses, such as *apoptosis* or preprogrammed cell-death, which eliminate cells that are at risk of undergoing neoplastic transformations.

Among sexually reproducing organisms such as humans, deleterious germ-line mutations can influence fitness outcomes in ways related to their pleiotropic effects on traits, meaning that they can influence the development of multiple traits simultaneously. This has led to the prediction that there exists a latent *fitness factor* among traits believed to signal the sensitivity of development to perturbation stemming from the presence of deleterious mutations (Penke et al. 2007). Thus, in sexually reproducing taxa, there should exist genetic correlations among seemingly quite distinct traits, encompassing aspects of physical condition, behavior, health, and reproductive viability, high-levels of which are *unconditionally favored* by *sexual selection* across different environments (Penke et al. 2007).

Under conditions where purifying selection occurs in proportion to the fitness costs of spontaneously occurring germ-line mutations, individual differences in and genetic correlations among fitness salient traits will be maintained within a population, as spontaneously arising deleterious mutations conferring few fitness disadvantages to their carriers (by virtue of recessiveness) can persist for many generations, with the addition of each new mutation cumulatively reducing the fitness of the lineage relative to others that are burdened with fewer such mutations. This mechanism by which variance is maintained with respect to fitness salient traits in a population is known as *mutation-selection balance* (Fisher 1930).

Sources and Rates of De Novo Mutations in Humans

Germ-Line Mutations

Paternal age is a major source of common germ-line de novo base substitution mutations (i.e.,

point mutations involving the substitution of single nucleotides) in humans and other eukaryotic taxa also. These new mutations arise via mitosis in germ-line precursor cells (spermatocytes) as a consequence of age-related declines in the efficiency of DNA repair mechanisms and are transmitted via meiotic cell division to the haploid genomes of spermatozoa (Kong et al. 2012). The generational base substitution rate varies widely between mammalian species. In humans, each year of paternal age adds approximately two of these mutations to the genomes of offspring, with fathers aged 35 transmitting around 70 base substitution mutations to their offspring. Mice (which have considerably shorter generation lengths) transmit about half as many mutations per offspring. The chimpanzee generational transmission rate is about equal to the human rate (Lynch 2016). It is important to note that these rates are based on the assumption of linear increases in the numbers of de novo mutations transmitted to offspring. In practice, DNA repair mechanisms undergo accelerated deterioration as a function of advancing paternal age, leading to an accelerating rate of increase in the numbers of de novo mutations (Kong et al. 2012). Maternal age is furthermore a source of additional de novo point mutations, but to a lesser degree than paternal age (the rate is around 0.5 de novo mutations per haploid genome per year of maternal age; Wong et al. 2016).

While paternal age is the principal source of common and mildly deleterious base substitution mutations in human germ cells, other less common classes of germ-line mutation also occur spontaneously, such as insertion-deletion events (i.e., where a single nucleotide is either added or removed), which occur at around 8 % of the base substitution mutation rate. Even less common mutations involving the addition or removal of large numbers of nucleotides such as copy number variation and chromosomal abnormalities also occur spontaneously. It has been estimated that once all sources of spontaneous germ-line mutations are accounted for, the numbers of such mutations transmitted to offspring may be as high as 100 per generation (Lynch 2016).

Human studies examining the influence of paternal age as a strong proxy for the numbers

of spontaneous germ-line mutations on offspring characteristics not only yield information about which trait variances may be maintained by mutation-selection balance but also yield evidence for the existence of the fitness factor, with paternal age effects having been found on diverse traits, such as the risk of offspring acquiring neurodevelopmental disorders such as autism and schizophrenia (Kong et al. 2012) and attention deficit/hyperactivity disorder (D'Onofrio et al. 2014), diminished physical attractiveness (Huber and Fieder 2014), and reproductive failure (i.e., childlessness) (Fieder and Huber 2015).

Finally, a critical factor that moderates a population's load of mutations is endogamy. More inbred (endogamous) populations being more homozygous for mutant alleles.

Somatic Mutations

Among somatic cell-lines, the rates of de novo mutation are much higher than the rate found in germ cells. Each mitotic event is associated with a de novo base substitution mutation rate that is on average 50 times that found in germ cells, with brain cells experiencing the lowest rate (eight times the germ-line rate) and skin cells experiencing the highest rate (112 times the germ-line rate) (Lynch 2016). Somatic mutation accumulation is a major cause of neoplastic transformation in defective cells that fail to be eliminated via somatic selection and may furthermore be a major source of contingency in terms of the underlying risks associated with developing certain neoplasms (Lynch 2016). Somatic mutations are also fundamental to *mutation accumulation theories of aging* (i.e., Medawar 1952), which treat the accumulation of mutations as a major source of the general and progressive cellular dysfunction characteristic of *senescence*.

Critically, somatic mutation accumulation is the principal mechanism through which selection occurs on mutation rate itself, as within an organism, both somatic and germ-line cells share common DNA repair systems, hence differential rates of somatic mutation can serve as a phenotypic target for selection on germ-line mutation rates (Lynch 2016).

The Mutation Load Paradox and Estimates of Human Fitness Loss Due to Germ-Line Mutation Accumulation

The Mutation Load Paradox

Although the human spontaneous germ-line mutation rate is relatively high when compared with that of other species, it is not especially high when considered in the context of human genome and population size and generation length (Lynch 2016). Despite this, it has been estimated that the human germ-line mutation rate, specifically under the assumption that approximately two out of the 100 or so de novo mutations will be harmful, would necessitate the reproductive failure of around 88 % of all humans born. In other words human populations should have undergone *mutational meltdown* whereby the fitness loss causes populations to shrink, increasing the rate at which these new mutations drift to fixation, leading to population collapse. In order to offset this each female should produce in excess of 16 offspring simply to maintain population viability. A *mutation load paradox* arises when this prediction is contrasted with the observation that reproductive failure and excess on this scale is not observed in human (specifically industrialized) populations (Kondrashov and Crow 1993).

One solution to the mutation load paradox is that relative fitness differentials between individuals of different genetic loads might constitute a source of cryptic or soft purifying selection in human populations, operating via factors such as sexual selection, and that large reproductive failure rates and excesses only emerge when mutation load-free genomes are used as the baseline for fitness comparisons against those with relatively high load (Lesecque et al. 2012).

Another interpretation of the paradox concerns the observation that high reproductive failure rates, especially among males, coupled with reproductive excess among females, were in fact a feature of historical, preindustrial populations. For example, among European populations in the year 1600 AD the average individual had around a 25–40 % chance of dying in infancy, a 50 % chance of dying during childhood (Volk and

Atkinson 2008), and only around a 40 % chance of fully participating in reproduction (Rühli and Henneberg 2013). The average family size was close to five in 1600s England (Arkell & Whiteman, 1998) – given the high rates of pre-term, infant, and child mortality, the *numbers ever conceived* would likely have been considerably higher. These historical Western infant and child mortality statistics are similar to those observed in contemporary hunter-gatherer populations (Volk and Atkinson 2008). Furthermore, the historical pattern of reproductive failure does not appear to have been random with respect to indicators of social and economic success, with far higher rates of reproductive failure being found among those with low relative to high social status, indicating that survivorship and reproductive success in this historical context might have been strongly coupled with elevated levels of certain competitiveness and fitness enhancing physical and psychological traits (Clark 2007).

It has been suggested therefore that historically observed levels of infant and child mortality, coupled with low reproductive participation and large compensatory reproduction among females, might account for a substantial portion of the variance in the estimates of both reproductive failure rates and magnitude of reproductive excess required by theory to purify de novo germ-line mutations in human populations (Woodley of Menie 2015). The paradox is therefore *only* apparent when the reproductive patterns of modern industrialized populations are considered, where perinatal mortality is extremely low (~0.5%; Woods 2008), infant and child mortalities are extremely low (~1 %; Volk and Atkinson 2008) and where the opportunity for full reproductive participation is extremely high (90 %; Rühli and Henneberg 2013).

The Consequences of Relaxed Purifying Selection in Industrialized Populations

The modern situation results from the extraordinary degree to which industrialized populations in particular have been shielded from potential sources of purifying selection stemming from reproductive impediments (such as stillbirth and infertility), disease, climate, famine, and violence.

Furthermore, conscious control over reproduction, facilitated by the wide-scale utilization of contraception, appears to have attenuated the correlation between potential indicators of low underlying genetic load, such as physical attractiveness and fecundity in some modern populations (Pflüger et al. 2012). Similarly, while paternal age predicts the risk of childlessness in contemporary samples of the US population, it does not appear to predict fecundity among the fraction of the offspring that go on to reproduce – a situation different from that of historical North American populations in which inverse associations between paternal age and offspring fitness have been observed (Fieder and Huber 2015). Lynch (2016) also notes the potential for cosmetic interventions to mask the effects of mutations on condition in modern populations. Findings such as these have been interpreted as indicating a potentially attenuated role for relative fitness differentials among individuals of differing genetic loads as a source of soft purifying selection in industrialized populations (Lynch, 2016; Woodley of Menie and Fernandes 2016).

These factors have therefore permitted population growth in industrialized nations to occur largely in the absence of major sources of purifying selection, which has facilitated an increase in the generational burden of germ-line mutations. Such mutations may have had significant fitness costs in the face of historical ecological stresses but no longer incur those same costs under modern milder conditions and are thus free to accumulate, perhaps exerting more subtle and direct effects on reproductive fitness. Consistent with this, Lynch (2016) has estimated that under the assumption of strongly relaxed purifying selection, it would be reasonable to expect fitness losses of approximately 1 % per generation among the populations of industrialized countries. Lynch also suggests that this generational fitness loss may even underestimate the true impact of mutation accumulation on fitness salient traits in these populations, as it does not take into account potential interactions between germ-line and somatic mutation rates, stemming from the damaging impact of the former on genes responsible for regulating the latter. Deregulation of the rate at

which somatic mutations accumulate might therefore lead to behavioral deterioration in human populations at a rate greater than the predicted loss in reproductive fitness, owing to the large genomic target size of the brain – with as many as 84 % of all genes in the human genome being involved in some aspect of brain development and maintenance (Hawrylycz et al. 2012).

This should not be taken to imply that there is absolutely no purifying selection operating on modern industrialized populations. Rarer forms of spontaneous mutation involving copy number variation or chromosomal abnormalities or relatively more common mutations interacting via *synergistic epistasis* (Crow 1997) can potentially cause significant functional and reproductive impairment, especially when such mutations lead to loss of viability early in development (such as in the case of spontaneous abortion, which terminates around 10 % of all pregnancies in the West). It is important to note also that some tiny subset of these mutations may even be beneficial for the fitness of certain individuals under certain conditions. Thus, purifying selection continues to operate, even under modern conditions, albeit likely on a much narrower range of the mutational spectrum than was the case historically.

Experimental Evidence for the Effects of Germ-Line Mutation Accumulation on the Fitness of Nonhuman Eukaryotes

There exists an extensive literature on the results of germ-line mutation accumulation experiments conducted on a variety of eukaryotic taxa with short generation spans, which has been taken as support for the approximately 1 % loss in fitness per generation estimate in humans (Lynch 2016). These experiments typically involve the maintenance of a line of descent in which, via experimental intervention, random individuals are selected for mating, thus eliminating the opportunity for purifying selection to operate on these populations via the effects of sexual selection. The impact of accumulated germ-line mutations on fitness is quantified via the measurement of offspring yields, viability (i.e., the proportion surviving to adulthood), and also via direct measurement of levels of fitness salient traits.

Insects

Much of the eukaryotic germ-line mutation accumulation research has focused on insects, with a number of studies having examined *Drosophila melanogaster* (the fruit fly) in particular. The earliest research into mutation accumulation involved fruit flies and found fitness losses (measured in terms of egg-to-adult viability) amounting to 1–2 % per generation in the case of populations that were heterogeneous for a specific chromosome that had been experimentally sheltered (via transmission through the male line) from the effects of purifying selection. Homozygosity for the target chromosome was associated with a larger fitness loss per generation (5–10 %) (Mukai 1964). Subsequent studies involving fruit flies replicated the finding of fitness loss via germ-line mutation accumulation; however, these studies also typically found smaller fitness losses and smaller rates of mutation accumulation than that observed by Mukai (e.g., Fernandez and López-Fanjul 1997). Importantly, it has also been found that in fruit flies the degree to which these mutations impact fitness is sensitive to ecological context, with substantially greater fitness losses occurring under conditions of competition relative to conditions where competition was relaxed (2 % per generation vs. 0.2 %) (Shabalina et al. 1997). This is precisely analogous to the situation as it pertains to the populations of industrialized countries, where aspects of behavior and physiology which have a potentially high sensitivity to spontaneously occurring deleterious mutations may have been far more critical for survival and reproduction historically under conditions of ecological stress than in relatively much more mild contemporary environments.

Indications of reproductive fitness loss have been observed in other insect species bred under mutation accumulation conditions such as in the case of houseflies (Bryant and Reed 1999) and flour beetles, which have been found to exhibit diminished starvation resistance relative to controls (Lomnicki and Jasiński 2000).

Yeasts

Mutation accumulation experiments involving yeasts (a unicellular eukaryote) have also yielded indications of declining fitness (when offspring

growth rates are compared with those of the parental generation), but with considerable line-to-line variability, indicating that some small minority of beneficial mutations may actually raise fitness when allowed to accumulate (Dickinson 2008).

Nematodes

Mutation accumulation experiments involving the roundworm *Caenorhabditis elegans*, which exhibits a lower spontaneous mutation rate than *D. melanogaster* (Lynch et al. 2008), find no indications of declining fitness when viability is used as an indicator (Keightley and Caballero 1997); however, behavioral deterioration in terms of diminished levels of behavioral traits believed to be highly fitness salient, such as those relating to chemosensing and locomotion, has been noted (Ajie et al. 2005).

Mammals

Recent research involving *mutator* strain mice (i.e., mice that are specifically bred for very high rates of germ-line mutation) have found evidence of rapid declines in reproductive fitness when bred under mutation accumulation conditions, relative to *wild-type* mice bred under the same conditions (Uchimura et al. 2015).

Potential Historical Micro-Evolutionary Manifestations of Germ-Line Mutation Accumulation in Humans

It is not possible to run mutation accumulation experiments on humans; however, historically, the nineteenth and twentieth centuries saw the biggest changes in evolutionarily significant aspects of the reproductive ecology of Western populations, such as dramatically falling infant and child mortality rates and rising opportunity for reproductive participation (Rühli and Henneberg 2013; Volk and Atkinson 2008), coupled with the wide-scale utilization of contraception. On this basis, it has been suggested that very recent microevolutionary indications of the effects of germ-line mutation accumulation on fitness salient traits might already be present in secular trend data on population levels of various physiological and psychological indicators of developmental stability (Rühli and Henneberg 2013; Woodley of Menie and Fernandes 2016).

Consistent with this expectation, secular trends towards reduced cranio-facial symmetry have been noted among both male and female European Americans, starting in the early nineteenth century. These have been interpreted as stemming in part from a microevolutionary trend towards declining developmental stability due to germ-line mutation accumulation in this population. Declining developmental stability has also been proposed as an explanation for parallel secular trends in the incidence of neurodevelopmental disorders, such as autism and ADHD, and also for historical increases in the incidence of sinistrality or left-handedness among Western populations (Woodley of Menie and Fernandes 2016).

Also consistent with a potential microevolutionary trend towards reduced developmental stability, Rühli and Henneberg (2013) presented several examples of *medical abnormalities* that have increased in frequency among the populations of industrialized countries over the twentieth century. These include a doubling in the prevalence of anomalous arteries, such as the median artery of the forearm and a decrease in the incidence frequency of individuals possessing the thyroidea ima branch of the aortic arch to zero. The opening of the sacral canal (spina bifida occulta) has also increased in prevalence among those born in the second-half of the twentieth century. Tarsal coalitions are also more prevalent in modern populations, as are skeletal pathologies, such as ossification of the posterior longitudinal ligament and of the spine and diffuse idiopathic hyperostosis.

A recent estimate of the impact of germ-line mutation accumulation on general intelligence (*g*) has been made based on the secular trend towards declining levels of cranio-facial symmetry – measures of *fluctuating asymmetry* and cognitive ability being mildly inversely correlated. The commensurate decline in *g* was estimated to be -0.16 IQ points per decade, with mutation accumulation possibly accounting for around 30 % of this loss or -0.05 points per decade. A small impact of mutation accumulation on *g* is consistent with the observation that *g* likely exhibits a narrow-band sensitivity to the mutational

spectrum and appears to be well canalized against genetic and environmental perturbation in development (Woodley of Menie and Fernandes 2016).

In considering possible historical microevolutionary trends such as these, Lynch (2016) urges caution, arguing that in order to adequately determine the contribution stemming from mutation accumulation, they need to be evaluated utilizing measurement models that can compellingly differentiate between genetic and environmental causes.

Conclusion

Research into mutation accumulation has generated a respectable body of theoretical and empirical work examining the phenomenon from multiple aspects. While germ-line mutation accumulation theory as it pertains to humans remains somewhat controversial, recent (as of this writing) synthetic summaries of this work (Lynch 2016) indicate that the accumulation of both germ-line and somatic mutations is nonetheless likely capable of producing relatively rapid declines in fitness (on the order of 1 % per generation) with noticeable effects arising over relatively short spans of time (i.e., a century). Critical theoretical factors that have not previously been considered in discussions of this phenomenon, such as the potential role of germ-line mutations that deregulate and enhance the rate at which somatic mutations occur and their potential role in behavioral deterioration, could form the basis for fruitful future research involving nonhuman eukaryotes, where behavior is rarely considered to be a key component of fitness (i.e., Ajie et al. 2005). The collection of systematic and detailed data on secular trends in behavioral and physiological variables, especially as these pertain to clinically significant measures, coupled with the use of measurement models that can tease apart causation should allow for fitness deterioration via mutation accumulation to be tracked.

Another potentially critical factor concerns the possibility that mutations with small, deleterious effects on behavior at the individual level can have disruptive effects on the *extended phenotype*

of social ecology in ways that feedback on and amplify the fitness costs to populations. For example, among prosocial species, mutations that lead to reduced sensitivity to social cues or degrade social learning ability could all have widespread effects on fitness, even among conspecifics who do not carry these mutations, but who are nonetheless dependent upon the maintenance of certain social ecological optima for their fitness (Woodley of Menie et al. 2017).

The idea that there may be a *group-selection* analogue of purifying selection may account for Calhoun's (1973) observation of the *behavioral sink* phenomenon in his *mouse utopia* experiments. Calhoun observed that when allowed unlimited resources and space, mouse populations inevitably reach a growth plateau, followed by a decline in fertility, terminating in colony collapse. The decline phase is characterized by the appearance of individual mice exhibiting apparently bizarre behaviors, such as obsessive grooming, a tendency towards either extreme solitariness or crowding, disinterest in communal reproductive activities, and asexuality.

Mice engage in a variety of reciprocal social interactions; they also practice communal nesting and nursing and territory marking behavior. The presence of an elaborated social ecology might be translating the deleterious effects of any mutations on behavior into much larger-scale fitness losses at the colony level in the case of Calhoun's experiments (Woodley of Menie et al. 2017). This mechanism may also account for why the mouse utopia populations did not simply stabilize around some equilibrium number of individuals but instead proceeded to collapse. Accumulating behavior-altering mutations may have been feeding back on the social ecology of the colony, dragging down the fitness of the colony and ensuring eventual collapse. This process of group-level purifying selection strongly resonates with Calhoun's (1973) own description of the terminal phase of mouse utopia:

Autistic-like creatures, capable only of the most simple behaviors compatible with physiological survival, emerge out of this process. Their spirit has died ("the first death"). They are no longer capable of executing the more complex behaviors compatible with species survival. The species in such settings dies. (p.86)

Social ecological systems might actually be quite fragile, containing "tipping points" which trigger group-level purifying selection and collapse once a certain critical load of behavior-altering mutations is present in the population. This is different from the classical mutational meltdown scenario, as it does not necessitate an initially small population in which deleterious mutations are drifting to fixation. Large and potentially genetically viable populations can in this scenario collapse simply via the deleterious pleiotropic effects of relatively small numbers of behavior modifying mutations on fragile features of social ecology. Within the context of human populations, this might help to explain the rapid transition into subreplacement fertility in many developed countries characteristic of the demographic transition. Total fertility rates in the United States, for example, fell from 3.7 in the period 1955–1959 to around 1.8 in the period 1975–1979 (Wattenberg, 1985) – a decline in organismal fitness of 51 % in just two decades – far in excess of what would be predicted on the basis of germ-line mutation accumulation under conditions of relaxed purifying selection alone. These fitness losses are furthermore biggest among those with potentially the lowest mutation loads, i.e. those with high social status. The idea that these rapid declines in fitness may stem even in some small part from the individually subtle behavior-altering effects of accumulated mutations on the generation of a natality-inhibiting cultural feedback loop is indeed a sobering thought, presenting yet another twist on the mutation load paradox, as here is a pathway through which mutations might yet be significantly impacting fitness, albeit indirectly. This possibility serves to amplify Lynch's clarion call that human mutation accumulation is a potentially major existential risk, deserving of our attention (Woodley of Menie et al. 2017).

Names and Titles

Jacob Peedicayil
Christian Medical College, Vellore, India

Synonyms

[Designation](#)

Definition

A title is a prefix or suffix added to someone's name in certain contexts.

As discussed elsewhere in this work (Peedicayil 2018), cultural inheritance involves the storage and transmission of information by communication, imitation, teaching, and learning. In this context, there is evidence that complex social behaviors like human altruism and mate choice (Rushton et al. 1986), social attitudes (Martin et al. 1986), personality (Eaves et al. 1999), and the human sex ratio (Lipatov et al. 2008) are culturally transmitted. The cultural transmission of such behaviors, for obvious reasons, will occur effectively only in an animal species that is social, i.e., where the members live in groups and interact freely with one another. Human beings are the best example of that type of animal species and the groups they live in are termed societies (Wilson 2000). Indeed, the famous Greek philosopher Aristotle

had stated “Man is by nature a social animal” (Aristotle 2015). All of man's unique social behavior is pivoted around the use of language (Wilson 2000).

Concerning names and titles, they are products of the highly advanced level of development of cultural inheritance found in humans when compared to other animal species. A title is a prefix or suffix added to someone's name in certain contexts (Wikipedia 2018). It can signify either veneration, an official position, or a professional or academic qualification. Titles include the following types: legislative and executive, aristocratic, titles used by knights, dames, baronets and baronetesses, judicial, historical, religious, academic, and military. Some titles are hereditary. Names and titles vary between different regions of the world and between peoples speaking different languages (Wikipedia 2018).

Narcissism

Scott W. Semenyina
University of Lethbridge, Lethbridge,
AB, Canada

Synonyms

Egocentrism; Grandiose self-esteem; Narcissistic Personality Disorder (NPD); Self-aggrandizement; Vanity

Definition

Narcissism is an epiphenomenon, arising due to various combinations and constellations of underlying traits and motivations. Although the underlying motivations and their behavioral outcomes are heterogeneous, the common core of narcissism is typified by a tendency for these individuals to be entitled, arrogant, self-centered, and vain, using their considerable social potency and tendency towards exploitative behavior to leverage themselves into positions of authority or social prominence (Holtzman and Donnellan 2015).

Introduction

Narcissism has existed in both the psychiatric and early psychological literature since the early 1900s, but this construct has only been under earnest empirical investigation since the latter half of the twentieth century (Raskin and Terry 1988). Only a minority (perhaps 1%) of the population surpasses the clinical threshold for a diagnosis of Narcissistic Personality Disorder (NPD). However, narcissistic personality traits are normally distributed within the population, meaning that there are far more individuals with narcissistic tendencies than there are people with pathological levels (Skodol et al. 2014). For that reason, it is often preferable to focus on narcissistic traits and employ the term “narcissist” to mean someone who scores highly on these traits instead of denoting someone who has received a clinical diagnosis.

Narcissistic traits are rarely associated with the internalizing symptoms of psychopathology (e.g., distress, anxiety, depression) (Miller and Campbell 2012). As such, some researchers have proposed that narcissism should only be considered pathological when it is comorbid with other personality disorders (reviewed by Skodol et al. 2014). In addition, narcissistic traits facilitate a social strategy that allows individuals to garner status, resources, and mating opportunities with desirable partners (Holtzman and Donnellan 2015). Thus, narcissistic traits expressed in appropriate circumstances may provide a selective advantage. Only considering the negative outcomes associated with narcissism under a pathological framework impoverishes our understanding of the construct. Greater insights are gained by considering the proximate and ultimate causes of narcissism, as well as its potential adaptive functions. In other words, a thorough understanding of whether or not narcissism is adaptive is only possible after considering: (1) the behavioral, personality, and interpersonal features associated with narcissistic traits; (2) the etiology of narcissistic traits among individuals, and whether they represent normal development or development gone awry; (3) the fitness benefits (or costs) of narcissistic traits to individual carriers; and (4) the roots

of narcissistic traits in the human lineage, and how they have been maintained across time.

The Narcissist in Context

Narcissism is not a unitary phenomenon. Modern researchers in the field differentiate between several prominent facets of narcissism – grandiose-exhibitionism, authoritative-leadership, and exploitative-entitlement – with the latter two slightly more common in men than in women (Grijalva et al. 2015). Grandiose-exhibitionism is associated with an overly ambitious and inflated sense of self, as well as a tendency to be gregarious and extraverted. Authoritative-leadership is characterized by a strong desire for leadership or authority in a group and the self-assured belief that one's leadership ability outstrips that of rivals. Exploitative-entitlement is marked by a pervasive belief that one deserves high social status and attention and a willingness to use manipulative tactics to get it. Generally, authoritative-leadership and grandiose-exhibitionism are seen as relatively more prosocial and less problematic (for the individual and the group) than exploitative-entitlement (Grijalva et al. 2015; Skodol et al. 2014).

Researchers have noted that individuals who score high on narcissism primarily employ two tactics to gain social status. One tactic is to use charm and assertive social styles to strive for admiration. The second tactic is to raise one's own social standing by bringing others' down (i.e., rivalry), by engaging in hostile and antagonistic social competition, derogating others, or devaluing their accomplishments (Back et al. 2013). The first of these tactics is most strongly associated with *grandiose* narcissism, which encapsulates the grandiose, leadership, and arrogant aspects of narcissism. The second tactic (rivalry) is more closely aligned with *vulnerable* narcissism – typified by emotional sensitivity, pervasive fears of rejection or abandonment, and exploitative tendencies (see Back et al. 2013; Foster et al. 2016; Grijalva et al. 2015). While there are several (nonmutually exclusive) ways to “be” a narcissist, they all share in common a self-centered entitlement,

social competitiveness, and striving for social validation.

Unsurprisingly, narcissistic traits tend to be positively correlated with self-esteem and extraversion and negatively correlated with agreeableness and conscientiousness (Holtzman and Donnellan 2015). Individuals high in narcissistic traits also report that they have an easier time starting new relationships, often perceive a greater availability of viable alternatives to current relationships, and report more lifetime sexual partners along with more favorable attitudes towards casual sex (i.e., higher *sociosexuality*) (Holtzman and Donnellan 2015). These associations are sensible given that converging lines of evidence indicate that narcissists are perceived as more attractive by others (Dufner et al. 2013). These ratings are likely a result of social charm and a focus on appearance enhancement, rather than narcissists being objectively more good-looking (Holtzman and Donnellan 2015). Despite these arguably positive outcomes, narcissistic traits such as exploitative-entitlement (Foster et al. 2016) and rivalry (Back et al. 2013) tend to be associated with poor social outcomes (social isolation, rejection, turbulent relationships, etc.). The confidence and charm of narcissists often facilitates social interaction, drawing people in to their constantly shifting social circles in the short term, whereas their tendency towards un-empathetic and aggressive social competition, along with their persistent ego-centrism, tends to push people away in the long term (Back et al. 2013).

A Selfish Mind: How Does Narcissism Develop?

Narcissism has been shown to be substantially heritable, with as much as 59% of trait variance being due to underlying genetic variation, and the rest resulting from the impact of environmental factors unique to the individual (Vernon et al. 2008). Such a pattern is indicative of an inherited propensity towards narcissism that then interacts with the experiences of the individual, crystalizing ultimate levels of the trait. Specifically, an early desire for social validation and prominence,

coupled with charming and extraverted social strategies, likely kick-starts a spiral wherein narcissists learn to regulate their behavior in ways that maximize the amount of positive social feedback they can garner, with desired outcomes only making these behavioral tendencies more likely in the future (Holtzman and Strube 2010). As noted above, the social strategy of narcissists tends to be relatively short term, and the substantial impact of genes on the development and expression of narcissistic traits calls into question how natural selection has tolerated such a selfish and (at times) exploitative strategy to exist in humans, a decidedly social species.

Selfish by Design? Natural Selection and Narcissistic Traits

Extremely high levels of narcissistic traits are often associated with significant social impairment, heightened alcohol abuse, aggression, and antisocial behavior (Miller and Campbell 2012). Furthermore, certain narcissistic traits (e.g., exploitative-entitlement, antagonistic rivalry) are related to psychopathic and Machiavellian tendencies, whereas the more prosocial facets of narcissism such as authoritative-leadership are associated with high self-esteem and more healthy interpersonal qualities (Foster et al. 2016). While it is tempting to see the socially corrosive nature of some narcissistic traits as an obvious disadvantage or indicator of pathology, such a value judgment should not cloud our evaluations of whether or not these traits (and their associated social strategies) are an advantage *to their carriers*. Indeed, the boldness of narcissists allows them to use their self-assured charm to gain the higher social standing they think they deserve. The enticement of enhanced social standing serves to ensure that narcissists both seek, and often obtain, social status, which in turn allows them to garner resources. In addition to striving for social dominance, narcissists tend to have a less restricted sociosexuality, which facilitates a short-term mating strategy in both men and women. For men, such a strategy usually entails maximizing the number of female sexual partners and hence

their reproductive output. For women, this likely means placing greater importance on the genetic quality (i.e., symmetry, health, masculinity) of her partner than on the partner's commitment to a long-term relationship. The combination of heightened status and a propensity to engage in short-term mating serves to explain both the proximate advantage to carriers and the ultimate origins of narcissistic traits in the human lineage.

Elevated status is a means of controlling resources (both social and physical), which confers a survival advantage. A short-term mating strategy serves to make a high number or greater quality of offspring more likely, with high status facilitating even more opportunity to engage in short-term mating. This dual selective pressure (first detailed by Holtzman and Donnellan 2015) helps to explain why natural selection would favor narcissistic traits and would allow them to persist across generations despite their potential social cost.

Adaptation or Disorder: Is Narcissism an Advantage?

The clinical psychology literature is replete with examples of the social malfunctioning of narcissistic individuals (see Skodol et al. 2014). Despite the potential pitfalls of narcissistic traits at extremely high levels (Back et al. 2013; Foster et al. 2016), new data are challenging old assumptions regarding the *benefits* of narcissistic traits at low to moderate levels (Foster et al. 2016; Holtzman and Donnellan 2015). The substantial heritability of narcissistic traits, and the way they facilitate not only heightened acquisition of status and resources, but also the securing of short-term mates, leaves open the possibility that narcissistic personalities can be thought of as a suite of (largely) adaptive traits, whose benefits tend to outweigh their costs. The psychopathology typically associated with narcissistic personality disorder (NPD) only exists in a small percentage of the population, and even these maladaptations may be better explained by comorbid personality disorders or other psychopathologies (see Skodol et al. 2014). In sum, narcissistic traits can be thought of as an adaptive cognitive and behavioral

style giving carriers not only the entitlement to take what they want (resources, status, desirable mates), but also the social tools to obtain them.

Conclusion

Narcissistic traits are associated with a grandiose sense of self, entitlement, and the use of bold and exploitative social strategies to gain social attention and prominence. While at extreme levels (i.e., NPD) narcissistic traits can be construed as maladaptive, the demonstrable social benefits associated with low to moderate levels of narcissism reveal the possibility of adaptive design via natural selection. Future research should test hypotheses associated with the positive benefits of narcissism, such as status attainment, favorable mating opportunities, and most importantly measurable reproductive output. Such considerations must be balanced against the potential social costs of narcissistic traits – dissolution of social relationships, social isolation, and antagonistic or hostile interpersonal styles. Only rigorous hypothesis testing will inform our understanding of narcissism as an adaptation, a disorder, or both, and reveal whether narcissists see success or failure when they peer into the (gene)pool.

[Fiction; Storytelling](#)

Definition

Representational format used to organize, store, and retrieve episodic information.

Introduction

Narrative is a representational format used to organize, store, and retrieve episodic information. As such, it is distinct from associated phenomena such as storytelling and fiction. Narrative includes any representation of a series of interrelated events, such as episodic memories, dreams, fantasies, plans, gossip and, of course, stories. The function of narrative can be inferred from its structural components, upon which there is widespread cross-disciplinary consensus: Cognitive psychologists and literary scholars alike agree that narrative requires a protagonist, setting, causally and temporally linked actions and events, and conflict and resolution. Collectively, these components illuminate the type of information that narrative organizes and stores.

Narrative Structure and Function

Arguably, the most essential component of narrative is causally and temporally linked actions and events (Scalise Sugiyama 2005). In a narrative, something happens: An event occurs or an action is performed that precipitates a subsequent series of events. Events are changes in the state of affairs (Rumelhart 1975) and can be external (e.g., changes in the physical environment) or internal (e.g., changes in mental state; Mandler and Johnson 1977). Actions are events caused by sentient beings (e.g., a boy throwing a ball at a window, causing it to shatter), as opposed to those caused by physical forces (e.g., an earthquake shaking a window, causing it to shatter). Because actions are behavior, and behavior is caused by mental states, narratives that involve sentient beings typically feature internal as well as external events.

Significantly, virtually all narratives involve sentient beings, or characters (Scalise Sugiyama 2005). Characters, in turn, are agents – entities

capable of having goals and capable of acting on those goals. Thus, narrative represents goal-directed action: events that agents cause to happen and agents' reactions to things that happen. Although dreams and memories may appear to lack this focus on agency, the individual experiencing the dream or memory is always an implied agent, because dreams are actual or imaginary events experienced or observed by ego, and memories are recollections of actual events experienced or observed by ego. Overwhelmingly, the agents that populate narrative tend to be human. Although animal characters are common in myth, folklore, and cartoons, they are almost always anthropomorphized: They may retain or be constrained by some of their nonhuman attributes, but they are endowed with a human psyche and human traits (e.g., bipedal locomotion, opposable thumbs, speech) that enable them to manipulate and interact with the environment in a decidedly human manner. Bugs Bunny is a case in point: Although he retains his classification as “prey animal,” he reasons, talks, walks, and manipulates objects as humans do. In myth, characters often take the form of inanimate entities and phenomena – e.g., celestial bodies, weather, topographical features – but like animal characters, they exhibit human intentionality and behavior. In sum, narrative exhibits a pronounced bias toward human-centered action. Even Kafka's “Metamorphosis,” in which Gregor Samsa has lost most of his human attributes, is about a human being with a cockroach body, not a cockroach with a human mind.

Because happenings play out in a physical universe, another key component of narrative structure is setting or the set of environmental conditions under which actions and events transpire (Scalise Sugiyama 2005). These conditions include topography and climate, physical laws and natural phenomena, and objects and their locations relative to one another. Because the human physical environment typically includes people, setting also has a social dimension, which includes such human-generated phenomena as laws, ideology, religious beliefs, norms, and manners. As in real life, the physical and

social conditions that obtain in a given narrative world constrain the kinds of events and actions that can occur.

The last critical component of narrative is conflict and resolution, which arise from obstacles to goal-directed action (Scalise Sugiyama 2005). An obstacle is a problem that must be solved in order for a goal to be achieved. For example, Cinderella is initially prevented from attending the ball by her lack of proper attire and transportation. In order to attain her goal, she must solve these problems. Resolution represents the outcome of conflict: It tells us whether or not the solution deployed by the protagonist solved the problem and whether or not the protagonist attained his/her goal.

In short, narrative is organized around the actions taken by a focal agent in pursuit of a specific goal, problems encountered in the pursuit of that goal (including the opposing goals of other agents), and solutions deployed to solve those problems. Experimental evidence supports the claim that narrative is organized around goals, complications, solutions, and outcomes. Studies have found poor recall for passages containing actions without complications or complications without resolution (Mandler and Johnson 1977). For example, Owens et al. (1979) found that knowledge of a character's motives improves recall of story actions and events. These findings suggest that events and actions are input into and retrieved from memory according to the goals they advance or impede.

When the components of narrative are combined, we end up with a representation of human goal-directed behavior and the set of conditions (including constraints and obstacles) under which it unfolds (Scalise Sugiyama 2005). The basic structure of narrative, then, is SETTING + AGENT + GOAL + ACTION + OBSTACLE + SOLUTION + OUTCOME. Humans appear to make sense of narrative by ascertaining the goals of the characters and using them as a schema for interpreting and organizing the characters' actions and feelings. This strategy mirrors the structure of the agency system, which uses intentional schemas (inference systems activated under specific conditions) to interpret and predict the

behavior of agents in terms of goals (Csibra et al. 2003). By the end of the first year of life, infants evince use of an intentional schema comprising three representational elements: the agent's action, the goal state implied by the action, and the constraints of reality on possible actions (Csibra et al. 2003, p. 128). Experiments show that infants are also capable of discerning contingent action or the modification of behavior in response to events or the actions of others. For example, infants look longer when an animated box continues to use a detour after an obstacle has been removed from its path (Csibra 2008). This suggests that infants expect agents to adjust their behavior in response to a change in conditions relevant to the goal-state (in this case, removal of the obstacle).

The representational elements of the agency system map neatly onto the components of narrative structure: "agent's action" maps onto AGENT and ACTION, "goal state implied by the action" maps onto GOAL, "the constraints of reality on possible actions" maps onto OBSTACLE and SETTING, and SOLUTION maps onto contingency. Narrative structure thus appears to emerge from cognitive mechanisms dedicated to tracking the goal-directed actions of agents in the world. Specifically, narrative appears to be a representational format that guides input and organization of knowledge about problems encountered – or that might be encountered – as agents pursue their respective goals. The AGENT component specifies the person or type of person (e.g., male/female, child/adult, married/single) who encountered the problem in question, the GOAL component specifies the objective and motive of the agent, and the ACTION component specifies the measures taken by the agent to achieve this objective. The SETTING component stores information about features of the local environment relevant to the agents' goals and is closely related to the remaining components: OBSTACLE specifies the nature of the environmental constraint(s) that impeded attainment of the agent's goal, SOLUTION specifies local strategies for surmounting the obstacle, and OUTCOME stores information about the effectiveness of solutions. In short, narrative structure "mimics the format in which experienced events

are mentally represented and stored in memory” (Tooby and Cosmides 2001, p. 24). Indeed, the agency system and narrative structure may effectively be the same thing: Each is dedicated to representing contingent relationships between sets of goal-directed actions. What we experience as “narrative” may simply be outputs of the agency system that rise to the level of consciousness.

Narrative, Storytelling, and Fiction as Discrete Phenomena

As a format for organizing and storing episodic information, narrative is distinct from associated phenomena such as storytelling and fiction. The ability to represent goal-directed action is not unique to humans: We may assume that all animals capable of agency are equipped with agency-detection systems (Barrett 2005). However, one thing that distinguishes humans from other animals in this regard is the ability to access other people’s narrative representations. Once language evolved, humans were able to share the narratives in their heads with conspecifics, and storytelling was born (Scalise Sugiyama 2005, 2011). This is a key point: Storytelling is interactive, narrative is not. Although all stories are built on a narrative framework, not all narrative is storytelling: Many memories, dreams, and fantasies never leave the confines of the mind. Thus, in contrast to narrative, storytelling is a behavior, a by-product of adaptations for (among other things) agency-detection, communication, cooperation, and theory of mind.

The fact that storytelling is a human universal (Scalise Sugiyama 2005) begs the question: What is gained by engaging in this activity? The answer lies in the function of episodic memory, the human memory system dedicated to storing personal experience. This system is hypothesized to provide the raw material for generating plans. As Schank explains, “Figuring out how to behave in a new situation is most certainly helped by being reminded of an old situation that is like the new situation. The old situation then becomes a guide to follow or even a guide to what not to do” (1990, p. 24). It has long been noted that experience is

retrieved from memory as stories (Schank 1990). Moreover, the structural parallels between memories and plans are striking. Both consist of agents, setting, and actions: A memory is a series of causally and temporally related actions that occurred in the past, and a plan is a series of causally and temporally related actions that can be taken to bring about a desired goal-state in the future. The content of plans is thus believed to derive in large part from our memories of past events: To make a plan, the mind consults past experience, gathers details relevant to the target goal, and assembles them into a series of actions tailored to attaining that goal (Schacter et al. 2007). This hypothesis is supported by neuroimaging data showing that the same brain regions are activated by the tasks of remembering the past and imagining the future, and by clinical research showing that memory impairment compromises patients’ ability to imagine future scenarios (Schacter et al. 2007). It follows that, if plans are built out of personal experience, then the greater and more varied one’s experience, the greater the variety of plans one can generate (Scalise Sugiyama 2011). The benefit of storytelling, then, is that it enables individuals to expand their episodic memory by acquiring experience vicariously: When we engage in story worlds, we observe the experiences of other agents and, in so doing, make them our own (Scalise Sugiyama 2011). As virtual experience, storytelling may also increase the audience’s sample size of actions and consequences, which may provide emotional and frequency inputs useful for the calibration of relevant decision-making mechanisms (Tooby and Cosmides 2001; Bechara and Damasio 2005).

Because storytelling involves information donation, it can be characterized as a form of cooperation. The benefit of storytelling for the audience is straightforward: Like all forms of teaching, it greatly reduces the costs of knowledge acquisition. Learning through direct experience is expensive: An individual must spend considerable time and energy seeking out experiences that will provide the needed information, and further time and energy on the experience itself. Moreover, trial-and-error learning can be

dangerous: She who learns from others that moose are dangerous during the rut has a better chance of surviving than she who learns this from personal experience. Social learning is also more predictable: An individual who relies on trial-and-error learning might not encounter the requisite learning experience by the time it is needed or when free from a more urgent task. Thus, like other forms of social learning, storytelling reduces risk and frees up time and energy that can then be invested in other important activities. It also exponentially increases the amount of knowledge that can be acquired in a lifetime: Through storytelling, humans can tap the knowledge of all the individuals in their social network, as well as past generations. Finally, by preventing knowledge from being lost when a person dies, the transmission of stories across generations enables human societies to accumulate and maintain large stores of information (Scalise Sugiyama 2011).

The benefits that accrue to the storyteller can be understood in terms of kin selection and social exchange. Telling stories to close kin may increase their chances of surviving and/or reproducing, thereby helping copies of the storyteller's own genes. Sharing stories with nonkin may motivate reciprocal behavior toward the storyteller, in the form of information or other valuable resources (Cosmides and Tooby 2005). Storytelling can also be characterized as a form of manipulation – specifically, as the strategic deployment of episodic representations to influence the beliefs and behavior of others (Scalise Sugiyama 1996). One drawback of being a highly social species is the ample opportunity group living provides for individual interests to come into conflict. Thus, there are times when a person can benefit from persuading others to modify their goals and behavior in ways that serve his/her interests. Stories are a highly effective means of disseminating information strategically, because both the timing and the content of the story can be tailored to the task at hand (Scalise Sugiyama 1996). For example, storytelling can be used to reinforce social norms by illustrating the rewards of compliance and the costs of deviance. The trickster genre is a case in point: Across forager societies, these stories are used to model antisocial

behavior and the negative consequences of engaging in it. With its implicit message that what befalls the trickster will befall other rule-breakers, this tactic provides a nonconfrontational means of chastising and threatening transgressors (Scalise Sugiyama 2011). Stories can also be used in conjunction with precautions, as seen in the use of monster stories by foragers to compel obedience from children (Scalise Sugiyama 2011). Informants report that they use these stories to discourage children from wandering off, crying at night, and depleting food stores. The monsters in these stories specifically target refractory children, and their predations are described in gruesome detail, which may serve to intensify the attentional salience and emotional valence of the precaution.

On this view, gossip is a subset of storytelling. As a means of exchanging social information and managing reputation (Dunbar 1996), gossip involves both cooperation and manipulation. And, like memories and plans, gossip consists largely of representations of goal-directed action – in this case, who did (or said) what to whom and to what effect. What distinguishes gossip from other types of storytelling is its focus on local social information: Gossip involves the exchange of narratives that reference agents, happenings, and entities in the participants' local environment. These representations are used strategically to provide alliance partners with beneficial information and to shape the beliefs and behavior of the gossip's social network in ways that serve his/her interests (Dunbar 1996; Scalise Sugiyama 1996).

Because narrative representations can be non-veridical, the terms *narrative* and *story* are often used interchangeably with *fiction*. This has led to confusing claims that literature is an adaptation. The term *fiction* refers to nonveridical representations intended to be understood as such and thus includes painting, sculpture, pantomime, and fantasies (Tooby and Cosmides 2001). Clearly, then, not all instances of fiction are instances of narrative or storytelling. Nor are all stories fictions. Fiction is a by-product of our evolved capacity to reason counterfactually – to think about things that aren't present, haven't happened, or don't exist. Counterfactual reasoning, in turn, is the bedrock of improvisational intelligence (the ability to invent

solutions to problems), which was critical to our species' colonization of the foraging niche (Tooby and DeVore 1987; Cosmides and Tooby 2000). As with other key human traits (e.g., bipedal locomotion, language), the importance of this faculty is indicated by its ontogenetic precociousness: The ability to understand pretense emerges by 15 months, and the ability to participate in pretend scenarios emerges between 18–24 months (Onishi et al. 2007). The agency-detection system begins developing even earlier, possibly by the sixth month of life (Csibra 2008).

Conclusion

Narrative, fiction, and storytelling are manifestations of the highly developed ability in humans to acquire, generate, exchange, and apply information (Tooby and DeVore 1987). The foraging niche is characterized by the use of complex techniques to extract nutrient-dense resources (Kaplan et al. 2007). Use of these techniques is supported by a wide range of knowledge and skill sets, which are impossible to acquire through trial-and-error learning alone (Boyd et al. 2011). Thus, occupation of the foraging niche is highly dependent on information exchange. Narrative is a format for representing actual episodic information that, in conjunction with the capacity for counterfactual reasoning, enables humans to generate hypothetical (i.e., fictional) episodic information. Combined, these two faculties enable the representation of possible chains of goal-directed actions. Like emergency drills, fictional narratives are simulations that enable humans to rehearse possible problems and test possible solutions. Language enables humans to exchange veridical and nonveridical narrative representations – to “recreate situations for others and to convey to them what has been found to be of interest and of value” (Bieseles 1993, p. 42) – exponentially increasing the ability to manage risk. Like slings, nets, and baskets, the generation and exchange of stories has “made possible the ‘carrying’ and thus the sharing of adaptively significant information” (Bieseles 1993, pp. 42–43), which in turn has greatly facilitated occupation of the knowledge-intensive human ecological niche.

theory, traveling efficiency hypothesis, postural feeding hypothesis, etc.), it remains that sometime in the evolutionary past (4–7 million years ago), the pressures of the environment affected locomotion to the extent that ancestral hominids began to travel on 2 ft. The shift from quadrupedalism to bipedalism may have been beneficial for a number of reasons, but it was also associated with skeletal changes that became problematic for women's reproduction. For instance, the hips developed larger joints, face changed laterally, and the diameter of the birth canal changed due to the shift in weight-bearing and balance. Further, although men's hips became narrower for optimal bipedalism, women's hip width remained constrained by both the need for a large enough birth canal for successful parturition (birth) and by sexual selection that may favor larger gluteus muscles. The remainder of this entry will focus on (a) the conflicting adaptations between bipedalism and large brains and (b) the mechanics of human parturition through the birth canal.

Narrowing Birth Canal

Anastasia Makhanova

Definition

As a result of the evolution of bipedal locomotion, women's birth canals narrowed, making parturition more complicated.

Introduction

Although there are several theories of how bipedalism evolved in humans (e.g., savannah-based

Implications of Bipedalism

Human bipedalism and large brains can be viewed as conflicting adaptations. Indeed, humans have much larger brains than any other hominin, and consequently, heads of human babies are also large. Perhaps due to this increased demand for prenatal brain development, human babies are born altricial (unable to move around or feed independently) and not precocial (able to move around and feed independently) like most nonhuman primates. The obstetrical dilemma hypothesis tries to explain the timing of pregnancy and labor by focusing on bipedalism and the narrowing of the birth canal (Weinger et al. 2008). During the shift to bipedalism (visible in *Australopithecus afarensis*), the pelvis and subsequently women's birth canals narrowed. However, the brain size in proportion to the bodies in *Australopithecus afarensis* was still small. Thus, it is likely that the birth canal only became a limiting factor to gestation later, around the time of *Homo erectus* when brain size started increasing more rapidly. The fossil record indicates that like humans, *Homo erectus* infants were likely

relatively altricial. Thus, the obstetrical dilemma hypothesis suggests that bipedalism constrained the human gestational period such that the babies have the most brain development possible but when they are still able to pass through the birth canal.

Implications of the Birth Canal

Because of the narrower birth canal and the morphological changes in pelvic structure associated with bipedalism, the mechanics of parturition in humans are somewhat peculiar in comparison to that of other species. Unlike most nonhuman animals, modern humans (like all immediate ancestors including members of the genera *Homo*, *Australopithecus*, *Paranthropus* and *Ardipithecus*) have birth canals that are wider sideways (hip-to-hip, transversely) than front to back (anteroposteriorly), and the inlet and outlet of women's birth canals are perpendicular. Furthermore, babies' heads and shoulders are wider in opposite directions as well. To the extent that babies first face in one direction to align their head with the birth canal and then turn in other directions for the rest of their bodies to pass, the physiological constraints mean that babies have to rotate as they are moving down the birth canal (Rosenberg and Trevathan 2002). The baby is normally born facing the opposite direction of the mother, unlike monkeys where the baby is facing the same direction as the mother. These pressures may have influenced the more social nature of human labor and delivery.

Conclusion

Bipedal locomotion evolved in response to pressures from the environment that likely were related to Resources and speed. However, for women, the change in skeletal morphology associated with upright walking facilitated a narrowing of the birth canal. This narrowing is thought to be related to the timing of parturition and the physiological and social aspects of human birth.

Definition

Language is an innate faculty which humans are biologically prepared to develop in contrast to other species.

Introduction

Naturalistic accounts of language acquisition, such as Chomsky's linguistic nativism, claim that our capacity for producing and understanding verbal correspondence is coded into our brains from birth. On its conception, in his 1959 review of Skinner's *Verbal Learning*, this type of explanation stood in contrast to the dominant empiricist views emphasizing learning and conditioning. Previously, researchers had explained linguistic development as a product of external variables, equating it to the vocalizations of other animals. A knowledge of grammar was then believed to be derived from domain general learning mechanisms, with individuals' capacities for language originating from the conditions of their physical environment. The nativist perspective challenged a prevailing focus on simplistic causal explanations for linguistic development. Instead it addressed the complex organs that allow for language to be produced and comprehended. Accordingly, though the specifics of a language were learned, the human capacity for it was thought to be the product of at least one species specific, genetically endowed, unit. That suggestion marked a paradigm shift in how linguists regarded the internal processes that determine language production and comprehension, and is sometimes credited with spurring the cognitive revolution.

Key Concepts

The nativist hypothesis reasons that language faculties emerge as organically as an ability to walk, with children's brains calibrated to extract content from limited samples of communication. Dedicated linguistic modules are therefore considered a fundamental part of the human genome. Thus rather than thinking of infants as blank slates, nativists characterize them as information processors in possession of an internal knowledge of syntax i.e., the principles and processes which govern form. Ergo people's capacity for organizing language is treated largely independent of that which they encounter in their surrounding worlds.

Chomsky (1980) notes that often a child's knowledge of grammar greatly exceeds the inputs and reinforcement they are given. Moreover, their daily use of language will often comprise novel strings of words that have not been previously spoken by or to them. They will also achieve their creative expertise despite rarely encountering negative evidence i.e., information regarding which strings of utterances are not grammatical. These occurrences make it infeasible that their language capacity is learned through habituation. Instead, despite the relative poverty of their stimulus, their brains must have an inherent means to generatively order its limited vocabulary into, or respond to, a seemingly infinite variety of combinations. Hence they can identify Chomsky's creation "colorless green ideas sleep furiously" as grammatically plausible despite it being semantically meaningless and the odds of them hearing it prior being improbable.

Chomsky (1980) labelled the chief tool, to this acquisition process, universal grammar. This term refers to a set of instinctive language-general principles of categories, mechanisms, and constraints including the ability to distinguish nouns from verbs, or function words from lexical words. One principle is syntax being dependent on structure rather than sequence. In English, a question form of the statement "Dean Robertson will cross the road" sees the third word shifted to before the first and second, to become "will Dean Robertson cross the road?" However, the same technique applied to "the slow chicken will cross the road" results in the ungrammatical form "chicken the slow will cross the road?" Inconsistencies such as this necessitate that speakers have a knowledge of structural components, rather than relying on linearity for clarity. In these examples, "Dean Robertson" and "the slow chicken" are both noun phrases, despite their variable forms. Whereas "will" is future-interrogative and so needs to be moved to the beginning in order to form a question.

Also included in universal grammar are parameters, referring to language-specific variations. For example, English is head-initial, with a noun of verb preceding compliments in the same phrase, while Japanese is head-final. It is these

specifications that allow speakers to create syntactically correct sentences that elucidate the relationships between subjects. The continuity assumption (Pinker 1994) suggests these innate parameters are reliable throughout people's lives meaning, once developed, young children's syntactic competence matches that of adults. The amount and scope of principles and parameters are still subject to rigorous debate, with researchers estimating there being anything from tens to hundreds.

Chomsky draws a parallel between thought and language, conceptualizing the latter to be a means of externalizing the former. In doing so he reverses the Aristotelian view of speech as sound with meaning, by labelling it meaning with sound. Yet he stops short of analyzing its adaptive origins in terms of the specific demands it had to meet. Other researchers have attempted to tackle this issue, so as to align knowledge of why humans have language with how it works. Notably, Dunbar (1993) explored its origins as a means to allow for vocal grooming, or gossip, by permitting simultaneous interactions between multiple members of a social group. Pinker (1994) agrees with language being an instinct akin to spiders weaving webs or beavers constructing dams. Though he suggests its purpose was to meet the reliance on knowledge that would have been crucial to the continued survival of hunter-gatherer societies. What both of these theories have in common is they support the nativist model in suggesting that language acquisition is not a byproduct of general learning tools.

This is not to suggest language acquisition is inevitable under nativist accounts. Rather, it has been claimed that children require access to samples of a naturally occurring inputs to initially stimulate the process. Lenneberg (1967) speculated a salient role of biological age, anticipating a critical period for language acquisition between 18 months and early puberty most people. Similar phenomena have been seen in cross-species, with researchers determining the effects that the timing of relevant environmental inputs can have on how attuned an organism's capacities are to the environment it has been exposed to e.g., imprinting in young animals. As per Chomsky's nativism, this

theory suggests language occurs through maturation instead of feedback. Lenneberg argued that this constraint is owed to a decrease in neural plasticity following hemispheric lateralization, where evidence for lateralization in language is robust.

Outside such a timetable, a child will be neither able to learn, nor meaningfully produce, language regardless of the inputs that follow. But provided this threshold is reached then they ought to learn it without a need for formal tuition. While the critical period has since been revised to a sensitive one, following some exceptional data, there appears to be a consensus that age is a key issue in learning a first language.

Evidence for Linguistic Nativism

The best evidence of linguistic nativism is in the seemingly streamlined process by which language, including sign, is acquired. From any other species, the most intelligent member would be unable to achieve that which we expect from any normally developing one of our own. Whether they are raised in a small mountain village, or a vast metropolis, children encounter equivalent milestones in the same order, despite often considerable variance among their inputs where Brown (1973). Their use will also be creative and not necessarily tied to a context, like the communication systems of other animals empiricists had thought analogous. It would be difficult to explain this humanity-wide mutual incidence, and the resultant grammatical consensuses, through nonbiological models. A uniform schedule, regardless of the quality of exposure, therefore hints at an innate underlying cause. Furthermore, to test the poverty of the stimulus argument Marcus (1993) explored the feedback that young speakers receive. In outlining the inadequate responses, that corrected meaning over grammar, he suggested internal factors and an innate knowledge must be crucial to constraining their generalizations e.g., past tense errors like "maked" or "goed."

A biological premise for language is further supported by consistent patterns of specific

linguistic faculties being deleteriously impacted, following damage to particular neurological regions, despite other cognitive capacities remaining intact (Hickok and Poeppel 2007). Modern imaging techniques, along with neuropsychological data, have revealed a network of regions specialized to comprehending language or articulation. Popular examples include the frontotemporal region, being localized to enunciation, the posterior temporal area being linked to understanding and the bridging tract to repetition. Combined these deficits reinforce language as a natural phenomenon, by highlighting a network of neurological substrates selectively dedicated to its function in the absence of obvious associations with other abilities.

Tragic childhood neglect stories suggest that the roles of these regions are subject to a sensitive period (discussed in Pinker 1994). Famously, Genie was rescued from prolonged isolation at age 13. While she regained some of her language capacities, including basic syntax and an ever-growing vocabulary, she was unable to apply or follow complex grammatical features. This deficit continued despite her being subject to a stimulus-rich environment which actively encouraged her to learn: something that would have nurtured her abilities according to empiricist accounts. In contrast, Isabelle was saved aged six and a half and was soon able to learn language and to use it as meaningfully as her peers. There are ambiguities surrounding the specific role of trauma, or the condition of each subject prior to their mistreatment. Even so, the stark difference in recovery between these examples advocates the existence of a time restricted window important for normal development.

A more routine illustration of the same phenomenon can be found in adults acquiring a second language, with some data showing a linear relationship between age of learning and subsequent struggles (Patkowski 1980). This line of research is considerably less conclusive than the case studies, with many notable instances of learners beginning in adulthood and still achieving fluency. Nevertheless, it is generally acknowledged that some aspects, such as picking up the native accent, are limited to children being raised

with a second language and not adults gaining one. For that reason it may be the neuromuscular components, such as phonology and pronunciation, which are subject to a sensitive period versus the contents of speech per se (Singleton 1995). However, comparisons with the unguided character of first language acquisition are potentially limited since adults learning a second language will typically do so intentionally.

Conclusion

Chomsky's seminal 1950s critique of empiricism provided a new layer of analysis for thinking about language, arguing that previous means had proven inadequate. Here, he extended a topic most frequently thought of through the lens of observable patterns and conditioning into an area ripe for interdisciplinary research. In particular, he called for a computational approach to linguistics that emphasized the species-exclusive nature of its bestowal. Universal grammar is a concrete theory that can be used to explain recurrent findings in the linguistics literature, including standardized procurement and selective dysfunction following lesions. That a young boy will learn to talk, in a way that his puppy never will, ties the aptitude to our unique biology. But prior to Chomsky, there was minimal consideration of its relative contribution or the mechanisms that may underlie it. Nativism changed this by adding modularity to the lexicon with which language, along with how other cognitive functions, was thought about. The details of this model, along with its evolutionary source and the comparative role of culture, are still hotly contested today. Nonetheless, the framework provides a means to better understand how humans are able to generate speech so effortlessly, be it for the most urgent or trivial matters.

Natural Selection

R. Haven Wiley
Department of Biology, University of North Carolina, Chapel Hill, NC, USA

Definition

Differences in the propagation of genes in a population as a result of survival and reproduction of organisms carrying those genes.

Introduction

Charles Darwin described natural selection in private essays in 1842 and especially 1844 (Darwin 1909; Glik and Kohn 1996, pp. 90–96). He then drafted a large manuscript on natural selection, which he left unfinished. It was subsequently overlooked until recently (Darwin 1975). Eventually in 1858, the Linnean Society published a version of his 1844 essay in conjunction with a communication from Alfred Russell Wallace. Wallace presented some related ideas, but not natural selection as we now understand it (Bulmer 2005). Soon afterward there appeared *On the Origin of Species / By Means of Natural Selection, / or the / Preservation of Favoured Races in the Struggle for Life* (Darwin 1859), which developed the concept in detail.

Introducing natural selection on the first few pages, Darwin emphasized the importance of variation among individuals, in particular hereditary variation, and a “struggle for existence,” in other words, competition, because “many more individuals of each species are born than can possibly survive”. He thus reasoned, “It follows that any being, if it vary however slightly in any manner profitable to itself ... will have a better chance of surviving and thus be *naturally selected*. From the strong principle of inheritance, any selected variety will tend to propagate its new and modified form.” He also recognized that natural selection is a means of the “coadaptation of organic beings to each other and to the physical conditions of life” (Darwin 1859, pp. 4–5).

Inherited differences in reproduction, as well as survival, can also lead to natural selection. Darwin emphasized this possibility when he proposed that differences in attracting mates or competing for them could lead to the special case of sexual selection. Attraction of mates proved to be especially controversial for Darwin’s successors. It implied the evolution of behavior, not just morphology. The idea that natural selection might produce preferences for mates, particularly by females, was inconceivable to most scientists in the late nineteenth century.

Darwin’s original theory thus included all of the essential elements of our current understanding of natural selection (see, for instance,

Maynard Smith 1998). Natural selection is a mechanism of evolutionary adaptation that results from a combination of heritable variation among individuals and differences in their survival or reproduction correlated with this variation. Natural selection does not require individuals to change, but it does require new variants to arise occasionally through reproduction. Natural selection requires more than individual differences in survival and reproduction. It also requires heritable variation in these differences. Darwin's presentation of natural selection included these elements but left many uncertainties, largely because the sciences of genetics and ecology had yet to come.

Basic Issues

When Darwin proposed natural selection, no one understood the mechanisms of heredity. Darwin himself conducted extensive experimental investigations of heredity and selection in domestic pigeons, but he was disturbed by his results. Offspring of differing parents often either combined the parental features or had intermediate features. Inheritance in this way, by blending of parental traits, could not produce adaptation by natural selection. Populations would instead converge on an overall average and then no longer change. Nevertheless it was apparent that pigeons did sometimes inherit parental features without complete blending. Within 50 years, examples of particulate inheritance and its infrequent mutations had been thoroughly verified. The inchoate field of genetics had provided Darwin's theory with the requisite mechanisms for heredity and variation, in the form of genes, each with variants (alleles).

Furthermore, it became clear that all steps in the process of natural selection – differences in survival and reproduction, heritabilities, and rates of mutation – were measurable and thus open to mathematical analysis. Within the first decades of the twentieth century, the mathematical theory of evolution by natural selection had established its basic principles. Evolution, that is, a change in the frequencies of alleles in a population of organisms, depends quantitatively on a balance

between selection, mutation, and migration between populations, as well as the inherent randomness in each of these three processes. Selection is included in equations for changes in allele frequencies by adding a coefficient to adjust the relative survival or reproduction of each allele. Random changes in allele frequencies become more pronounced in smaller populations. Within small populations, rare alleles are more likely to be lost, and one allele is likely to become “fixed” (universal), so random genetic variation among individuals is reduced. On the other hand, random genetic variation among small populations is enhanced.

Concurrently with the theoretical advances, experimental studies in laboratories and quantitative studies of populations in natural conditions confirmed all of these processes (Dobzhansky 1937). It was found that individuals in a population often differ in survival or reproductive success, these differences are often heritable, and genetic variation depends on the sizes of populations. Hoekstra et al. (2001) and Kingsolver et al. (2001) provide reviews of the prevalence of selection in natural populations.

The theoretical study of natural selection and evolution has in recent decades developed great sophistication in exploring the manifold complexities of population size and structure, mating systems, social interactions, migration, and isolation. Empirical studies continue to document the relevant processes. These studies, especially in natural conditions, face challenges in verifying small effects of selection and complex contingencies, in conjunction with randomness in finite populations. These effects are just the sort that theoretical investigations tend to explore.

Despite these theoretical and empirical advances, natural selection still has its perplexities and confusions. Natural selection, those who study it agree, results from the correlated consequences of individual variation, heredity, reproduction, survival, and competition and produces adapted change in the composition of a population. In various contexts, these components have raised many contentious issues. Is natural selection the result or the cause of adaptations? What kinds of variation and heredity are affected by natural selection? How do survival and

reproduction interact? What about cooperation as well as competition? Even more important, is natural selection fundamentally misleading? On the one hand, is it so simple that it reduces to a tautology and explains nothing? On the other hand, is there enough complexity to explain the emergence of cooperation, culture, language? Is it even specifically a biological process?

First, a clear definition is needed. Natural selection, along with mutation, migration, and drift (randomness), produces evolution. Evolution is a change in the genetic structure of a population of organisms. In the simplest case, it is a change in the frequencies of alleles in the population. Natural selection then occurs when individuals differ in their survival or reproduction in ways associated with differences in their alleles. It is important to point out that natural selection does not result merely from differences in survival or reproduction of individuals. It also requires heritability of those differences. Natural selection is thus a change in the frequencies of alleles in a population as a result of differences in the survival and reproduction of individuals that carry those alleles. It is a matter of arithmetic: in any population, genetic variants spread when they leave more copies in successive generations.

Such a definition resolves one basic issue above. Natural selection is not tautological. It is not survival of those that survive. It both results from adaptation (of individuals) and produces adaptation (of populations). The general principle is indeed simple and self-evident. If individuals with particular features survive and reproduce better than others (call these individuals adapted) and if reproduction preserves features of the original, with occasional variation, then a population will accumulate adapted individuals. This concatenation of simple arithmetical steps is unarguable.

Heritable Differences

The mechanisms of heredity and variation have become progressively clearer and their complexities better understood. Within 50 years after the *Origin of Species*, the particulate inheritance of discrete features of plants and animals had

become the subject of rapidly expanding research. Fifty years later, a century after the *Origin*, the molecular structure of a gene had been discovered. Now, some 60 years later, many complexities of molecular genetics have been investigated, although challenges remain.

The basis for heredity is an organism's genome, strands of DNA of enormous length duplicated in each of its cells. Segments of this DNA encode the amino acid sequences for several tens of thousands of different proteins, which compose much of each cell's structure and regulate its vital functions. Other segments encode a large variety of RNA molecules, which themselves (without translation into proteins) provide a diverse array of regulatory actions. An organism's DNA also includes parasitic components, which hitchhike on the mechanisms for duplication or which subvert the mechanisms for translation for its own purposes. All of these direct and indirect effects of DNA provide mechanisms for heredity and opportunities for variation.

The genome, we now know, is not the only way that parents can transmit their features to their progeny (Jablonka and Lamb 2014; Robert 2009). The cytoplasmic contents of ova (and sperm, in special cases) are transferred to zygotes and influence their development. The DNA in mitochondria is the primary example of maternal cytoplasmic inheritance, but other components of the cytoplasm can also influence development.

Bonding of methyl groups to nucleotide bases in a segment of DNA can decrease its rate of translation to proteins. This inactivation of DNA by methylation is catalyzed by enzymes encoded by DNA elsewhere in the genome. In some cases, methylation is also promoted by environmental conditions, such as temperature or stress. Furthermore, patterns of methylation are sometimes passed to progeny with the parents' DNA. Plants and animals differ in which nucleotide base is methylated (cysteine in animals, adenosine in plants) and also in the rates of transfer to progeny (greater in plants, which lack the isolated lines of germ cells in animals). Gradual loss of methylation in successive generations eventually attenuates its effects. Nevertheless, rates of methylation and rates of reversion vary markedly in different

regions of DNA (Van der Graaf et al. 2015). Yet whether or not patterns of methylation persist across many generations, natural selection can enhance or diminish their influence on the activity of DNA, just as it can adjust other molecular mechanisms that regulate expression of DNA. Methylation, often called “epigenesis,” meaning “beyond genetics,” expands the possibilities for natural selection. With its susceptibility to environmental influences and its progressive loss, it provides a mechanism for heredity more flexible and less stable than other ways to regulate DNA.

Still less stable influences on development, but nevertheless hereditary, can result from direct responses to an environmental feature sustained across generations. Learned habits and customs are examples that can propagate in families and populations of interacting individuals. The seasonal territorial boundaries defended by many songbirds, as well as features of their songs, provide examples of learned information transferred across generations in organisms other than humans.

Consider even a suggestion by Lamarck that persistent abrasion of parts of the body could result in inheritance of calloused skin. This “inheritance” would occur in human populations, for instance, if children tended to follow parents’ predominant activities, such as using hands for heavy work or bare feet for walking.

Direct environmental influences have often not been accepted as natural selection. Yet the capability for developing callouses, for instance, is likely to require a predisposition to respond to abrasion by thickening of the epidermis, and such a predisposition might depend on particular structural or regulatory proteins (or methylation of particular segments of DNA, or both), all of which would require particular variants of DNA. In other words, development of callouses would depend on a particular interaction of genes and environment. In this case, for a particular genetic structure of the organism, development of callouses would be especially sensitive to environmental conditions.

Other environmental influences on development, including learning, also require physiological mechanisms and predispositions to respond to

features of the environment and thus are also subject to adaptation by natural selection.

The result can take different forms. Development might vary continuously with some environmental feature. Alternatively, developmental switches might produce several alternatives in response to particular environmental features. In other cases, development might be especially sensitive to an individual’s genome, rather than to its environment. An example is human growth to a particular height, in a population of well-nourished individuals. In such cases, genetic influences are more or less “canalized” within a range of frequently encountered environments. Across the entire spectrum from predominant influences of the environment to predominant influences of the genome, the development of an organism is always an interaction of its particular genome and its particular environment.

The influences on an individual’s development span a spectrum of stability from genome to environment. DNA, one of the most stable organic molecules known, retains some of its structure even in the remnants of organisms that died tens of thousands of years ago. In contrast, the most variable features of the environment, for example the weather, can hardly be predicted from day to day. The development of an individual depends on responses to this entire spectrum of influences. At one end is an archival plan, at the other an immediate context.

No successful construction can rely on one of these alone, neither plan nor context. Context alone has too many possibilities; a plan has too few. Trying to build without a plan is just as likely to fail as insistence on following a plan. Successful construction, as much as successful development, results from adaptations at various levels of stability and flexibility. A “tried and true” plan is important. So is attention to immediate context. Success requires stability across generations as well as flexibility in momentary responses.

Development of an organism, its construction, is thus a plan instantiated in a particular context. All contextual influences during the lifetime of an organism, whether temperature, nutritional, or sensory, are mediated by proteins encoded by the genome. An individual’s response to any stimulus

depends on its current state as much as it does on the impinging stimulus. An individual's behavior, for instance, is at any instant an interaction between its present state and the incident stimulation. This interaction of current state and immediate environment continues through the successive, incremental stages of development, throughout an organism's life.

Each individual's survival and reproduction thus result from an interaction of its current state and its current environment. This process occurring in all individuals of a population produces natural selection. So the progressive interaction of genes and environment during an individual's development is embedded in a longer interaction of genes and environment in the evolution of a population of individuals. The pattern of an organism's development is embedded in the pattern of a population's evolution. Natural selection, an interaction between genomes and environment directing the evolution of a population, results from interactions of genome and environment directing the development of each organism.

As a result of such pervasive interaction, we can draw four general conclusions about structure and context: (1) nothing is *determined* by structure, (2) nothing is *determined* by context, (3) everything is *influenced* by structure, and (4) everything is *influenced* by context. In these four conclusions, the general terms, *structure* and *context*, summarize a variety of more specific alternatives: *plan* and *reality*, *physiological state* and *sensation*, *genotype* and *environment*. Each pair of alternatives, substituted for *structure* and *context* in the four statements, produces equally general conclusions.

Variation in Heritable Features

Natural selection, as just described, might produce stability or flexibility in development, to any degree between extremes of "canalization" and "plasticity." In any particular case, the result depends on the nature of both genetic variation and environmental variation.

Genetic variation in a population is produced by mutations in the genome, by genetic drift

(random variation in reproduction or survival), and by migration to and from other populations. R. A. Fisher (1930) first emphasized the importance of variation in his "Fundamental Theorem of Natural Selection," which states that evolution is proportional to genetic variation, for any strength of natural selection. G. R. Price generalized this equation, by partitioning the change in genotypes in a subsequent generation into the covariance between genes and environment. Price's equation makes it clear that this principle can apply to any change, including learning as well as evolution (Okasha 2008; Grafen 2015; Queller 2017). Variation is fundamental to natural selection just as it is to learning.

One consequence is that natural selection must depend on mutation rate. This rate determines the rate of increase in genetic variation in a population; the rate of decrease in genetic variation, in contrast, depends on random loss (genetic drift) and thus on the size of a population. Migration affects genetic variation also, but the principles are similar. Mutation rates, by their effects on natural selection, influence the rate at which a population adapts to environmental change.

The mutation rate at any locus in the genome depends on the regulation of duplication and repair of DNA by proteins encoded elsewhere in the genome. If so, mutation rates might evolve to adjust the stability of DNA at particular locations in the genome. Natural selection might adjust these rates to the rates at which relevant environmental features change. It is known that segments of DNA (and thus the corresponding proteins) differ in their mutation rates. Not well understood, however, is whether or not mutation rates themselves evolve to adjust the rate of evolution by natural selection at different places in the genome.

Environmental variation comes in a spectrum of periodicities, with durations from seconds to many centuries. The stability or plasticity of development or evolution depends on how natural selection responds to different degrees of environmental periodicity. Environmental variation with periods much shorter than an individual's life is best accommodated by direct influences of the environment on an individual's development. Environmental variation over periods of one or a

few generations is often better accommodated by a few alternative sub-plans for development. Variation over intervals of many generations is handled most efficiently by revisions of the basic plan. For biological organisms, these three alternatives correspond respectively to learning, developmental switches (Pfennig 1990), and genomic encoding. These three alternatives are of course points in a continuous spectrum from flexibility to stability. Each of these developmental alternatives results from an interaction of environment and genome, with progressively decreasing reliance on environmental flexibility and increasing reliance on genomic stability.

Nevertheless, the entire spectrum of developmental alternatives rests ultimately on the genome, the most stable form of inheritance. The genomes of organisms must encode the capabilities and predispositions for genetic or environmental stability, for developmental switches, for temporary methylation, or for flexible learning – for development in response to long-term, medium-term, or short-term variations in the environment. The development of individuals thus cannot be separated from the evolution of populations. Natural selection occurs at all periodicities of environmental variation.

Cooperation and Competition

The evolution of cooperation has created another challenge for natural selection. Darwin's initial summary of natural selection emphasized a "struggle for existence," inspired by Malthus' observation that reproduction can outrun resources for survival. This "struggle" implies competition. Ecologists now recognize two forms of competition, aggressive and exploitative. In the first case, direct interaction between two individuals results in greater access to a limiting resource for one of them. In the second, one individual acquires proportionately more of a resource as a result of its greater efficiency at locating or harvesting it, without any direct interaction with other individuals. Both forms of competition can result in the "struggle" Darwin imagined as the basis for natural selection. In his discussion of

honeybees, Darwin acknowledged the challenge that such competition presents for the evolution of cooperation.

Simplistic explanations for the evolution of cooperation prevailed for more than a century after *The Origin of Species*. During the middle decades of the twentieth century, for instance, it was widely assumed that cooperation would prevail in a population whenever cooperating individuals gained an advantage over non-cooperators. Furthermore, it was assumed that competition between groups of cooperators and groups of non-cooperators would lead to the evolution of cooperation.

A path-breaking book, *Adaptation and Natural Selection: A Critique of Some Current Evolutionary Thought*, challenged these assumptions in their naive forms (Williams 1966, also Dawkins 1976). Cooperation might provide advantages to individuals and thus favor the spread of alleles associated with helping, but it is also necessary to consider possibilities for the spread of alleles associated with *exploitation* of cooperators. Such "cheaters" would have the benefit of accepting help from cooperators without the cost of reciprocating. Cooperators then face the prospect of becoming "suckers," by providing benefits to others that do not return them. Simple math shows that alleles associated with cheating spread at the expense of those associated with helping, even to elimination of the last helper alleles from a population. Group selection, the selection of cooperative groups in competition with non-cooperators, thus appeared in a new perspective. Cooperation had to spread *within* groups before it could spread by competition *between* groups.

Even if cooperation occurred mainly in small and relatively stable groups of individuals, so that some groups might by chance lack individuals with alleles for cheating and cooperators could prosper, these groups would remain vulnerable to any new alleles associated with cheating, which would then spread by natural selection to exclude cooperation.

Nevertheless, persistent cooperation has been documented for many kinds of organisms (Koenig and Dickinson 2016). It is clear, though, that special conditions apply. First, cooperation must

spread within groups before it can spread by selection among groups. Second, reciprocity is a key to cooperation: costly helping must have compensating benefits in return. Third, alleles associated with cooperation can propagate within families as a result of kin selection, a special case of natural selection.

The evolution of cooperation under these constraints requires alleles associated with a behavioral tactic more complex than a simple heritable tendency to help. Perhaps the simplest effective tactic is to try helping occasionally but to continue only if reciprocation ensues (“win stay, lose shift” or WLS). For instance, sedentary individuals, restricted to interacting repeatedly with a few neighbors, can evolve neighborhoods of cooperation, provided neighbors have alleles predisposing them to initial cooperation rather than cheating. More effective is a capability for identifying and tracking individual partners (Wiley 2012, 2015). Alleles associated with tit for tat (WLS directed at recognizable partners) then permit a cooperative resolution of the prisoner’s dilemma. With further behavioral elaboration, individuals might have capabilities for tracking multiple partners. Then alleles associated with such tracking (combined with those for predictable reputations of helping others) can make diffuse reciprocity advantageous (Nowak 2006; Nowak and Highfield 2011).

A different sort of advantage accrues to helping when it is directed toward genealogical relatives. In kin selection, an allele associated with helping kin can spread provided the cost to the helping individual is less than the benefit to its relative, devalued by the probability that the relative carries a copy of the same allele (in excess of the probability in the population at random). The mathematical condition is $C < rB$, where r is the coefficient of genealogical relatedness (the relevant probability when an allele for helping is rare). Individuals do not have to recognize kin directly; they can reliably interact with kin simply as a result of, for instance, birth in the same nest.

Investigation of a wide variety of animals and human societies shows that helping is frequently directed to close kin. Nevertheless, clear exceptions occur. Furthermore, it is rare that the

quantitative condition, $C < rB$, is met. The latter difficulty can be overcome by a combination of some reciprocity in addition to close kinship. Kinship and reciprocity should complement each other in the evolution of cooperation by natural selection.

A further complexity can favor the evolution of cooperation within groups: policing. If cooperators join forces to punish or exclude cheaters, the extra cost imposed on cheating can make it less competitive in relation to cooperation. In this case, the cost to cooperators of policing must not reduce the benefits of cooperation too much. Also, avoiding the costs of policing (while yet enjoying its diffuse benefits) becomes a second-order form of cheating. Finally, if policing results in the expulsion of cheaters from a group, so cheaters face the possibility of receiving no benefit whatsoever from membership in the group, then selection might favor a form of stealth-cheating by sophistication in evading detection. Alternatively, super-cheating might consist of complete disruption of a group in the expectation that strictly individual competition might provide greater advantages for a cheater than expulsion from a cooperative group.

This spectrum of possibilities for the evolution of cooperation by natural selection involves increasing behavioral complexity. Some of the options thus might apply only to humans. For instance, although cooperative interactions with kin are widespread among nonhuman animals, only a few nonhuman primates have enough complexity of individual recognition to support the formation of reputations (Wiley 2012). Evidence for policing by animals, even primates, is also sparse (Flack et al. 2005; Beisner and McCowan 2013). On the other hand, neither theory nor field work has yet plumbed the complexities of helping and cheating, either animal or human.

Constraints on Natural Selection

In the early years of population genetics, a controversy arose between two of the pioneers in this field. Fisher’s Fundamental Theorem suggested that natural selection would move populations in

a particular environment toward ever greater adaptation provided a source of genetic variation, such as mutation, persisted. Sewall Wright argued, on the other hand, that natural selection usually moved populations toward a local optimum in an adaptive landscape with multiple optima. An adaptive landscape, as Wright imagined it, is a multidimensional map of the adaptation of organisms as a function of possible genotypes, in other words, of all possible combinations of alleles at every genetic locus (Wright 1932, 1986). An adaptive landscape in this sense applies to a particular environment. Only if each allele evolved independently would natural selection lead to a unique, maximally adapted genotype for this environment, as Fisher indicated.

Interactions among alleles, as Wright argued, make multiple local optima for genotypes nearly inevitable. Constraints on interactions of alleles at the same locus or at different ones would produce adaptive peaks in any environment. Optima in such an adaptive landscape result from trade-offs in the interactions of alleles at the same or different loci, in one or multiple individuals. Such interactions are frequent in genomes and populations. Any one protein often affects more than one cellular function or trait (pleiotropy), and any one trait or function is often influenced by more than one protein (epistasis). A change in one trait might benefit survival or reproduction only if a concurrent change occurs in another trait. Furthermore, social interactions can involve traits with advantages for one individual but disadvantages for another, or traits with advantages only when present in both individuals concurrently.

Alleles associated with such traits often do not spread in a population when rare. For instance, during sexual selection, alleles associated with a female preference for a male trait do not spread unless their frequency in the population exceeds a threshold (or their genetic correlation with alleles for the male trait exceeds a threshold) (Lande 1981; Kirkpatrick 1982; Andersson 1994). In general, alleles associated with producing a signal cannot spread when alleles for responding to the signal are too infrequent, even if a response would benefit a signaler. Vice versa, alleles for responding cannot spread when alleles for

signaling are rare, even if a response to a signal would benefit the receiver. Only in a population with enough of both sorts of alleles can they both spread (Wiley 2015).

The situation is even more constrained when rare traits have costs for individuals. For instance, when a preference takes time or a signal entails exposure to predators, these individuals are often subject to increased mortality when their counterparts are not quickly located. The associated alleles are lost from the population by natural selection even more rapidly than by random genetic drift alone. Furthermore, alleles for mate preferences interact in counter-intuitive ways with those for ecological differences (Servedio and Kopp 2012; Servedio and Bürger 2014).

Interactions between heritable variants, whether pleiotropic or epistatic, place constraints on evolution by natural selection. Thresholds and isolated adapted optima result. Only genetic drift or extraordinary mutations can move populations past hurdles or valleys where genotypes are associated with disadvantageous traits of organisms (phenotypes). Because alleles cannot persist unless organisms associated with them survive and reproduce disproportionately, thresholds and isolated optima are not easily surpassed. When multiple traits or genes are required for an overall advantage in survival and reproduction, the probability of overcoming disadvantages decreases.

In some cases, it is possible to circumvent hurdles by coopting unrelated traits or functions (Wiley 2017). In the course of natural selection, fins can become repurposed as legs and wings, just as ocelli can become photographic eyes, comfort movements can become signals, and perhaps habituation can become associative learning. Without cooptation of simpler traits to produce more complex ones, natural selection can overcome thresholds and isolated optima only by waiting for fortuitous mutations, either simultaneous combinations or discontinuous effects, occurrences sometimes called “hopeful monsters.” Perhaps, in the long run, such events can occur. If so, evolution would inevitably lead to maximal adaptation of organisms, as Fisher indicated, despite the thresholds and local optima created by interacting alleles in the short run.

Nevertheless, these interactions prolong, even when they do not prevent, evolution toward global optima by natural selection.

Empirical studies of natural selection have so far infrequently reported pleiotropy and epistasis of alleles under selection (Kingsolver and Diamond 2011). Perhaps these interactions in fact seldom constrain natural selection. On the other hand, the constraints might make selection more difficult to study, so that reports have focused on selection with little constraint. It is also possible that selection itself, over sufficient time, tends to reduce these constraints. For instance, duplication of a gene occurs frequently in the course of evolution, often followed by differentiation of the functions of the “daughters.” Duplication and subsequent differentiation would reduce the constraints of pleiotropy on further progress of natural selection. The mechanism of duplication is itself regulated by other proteins and thus subject to evolution by natural selection.

Interactions between alleles at the same or different locations in DNA or between different consequences of the same allele, and the corresponding interactions between traits of organisms, all produce constraints on the progress of evolution by natural selection. As the complexity of organisms increases, it seems possible that these constraints become ever more complex and thus the constraints on evolution by natural selection ever more obstructive. Natural selection itself might produce still more complex genomes to reduce these constraints somewhat.

Evolutionary Computation

Biological evolution is not the only framework for discussing natural selection. Nothing precludes a generalization of its principles far beyond biological evolution. Optimizing structure by means of heritable variation and selection applies equally to evolution, epigenetics, and learning. In recent decades, it has also been applied to computation and molecular synthesis.

Evolutionary computing provides a way to optimize an algorithm (analogous to optimizing

genetic structure) by systematically modifying its components (mutation) and then selecting those versions of components that optimize the output (organism or phenotype) for particular purposes (environments). The process is usually incremental and progressive like natural selection in biological evolution: mutation and selection occur repeatedly until a local optimum is reached.

An example is the use of neural networks to discriminate sets of inputs. In this case, a series of similar inputs is presented to a network of interacting nodes, each of which can promote or inhibit activity in other nodes and all of which combine to provide a response to each input. Randomly adjusting the interactions of nodes at each generation and then selecting those variants that improve discrimination between different sets of inputs eventually yields the best performance possible. In a similar way, pharmacologists search for optimal molecular structures by progressively altering the components of complex molecules (for instance, the sequences of amino acids in synthesized proteins) in order to maximize medical benefits and to minimize undesirable side-effects.

Evolutionary computing or adaptive synthesis occurs in a multidimensional adaptive landscape just as biological evolution does. The adaptive landscape is the performance of an algorithm or synthetic molecule as a function of the hyperspace of possible structures (nodes and parameters or types and positions of chemical functional groups). Any solution encounters two widely discussed problems: too much precision to capture an entire adaptive peak; and too little accuracy to capture a global peak. In evolutionary computing, the first problem is called “overfitting” (Domingos 2012; Srivastava et al. 2014); it applies to algorithms that perform well on initial data but poorly on similar, but previously unseen, data. Such an algorithm has evolved to a local peak but too narrowly. In other words, an algorithm with overfitting has learned some of the noise (non-generalizable features) in the initial data as well as some of the signal (generalizable features). It has learned too much.

Ways to reduce overfitting include early stopping (as soon as errors on previously unseen data increase too steeply) and limitations on structural and parametric complexity (by reducing the number of nodes and interactions and their weights). Constraining weights of parameters often reduces overfitting by reducing the unpredictability of responses to similar but previously unseen data. All of these procedures rely on testing algorithms with unseen data. In terms of an adaptive landscape, they require testing performance on nearby parts of the landscape.

The second problem of evolutionary computing also has its analogue in biological evolution. Natural selection moves structures toward adaptation to a local optimum in the adaptive landscape and thus can miss a global optimum. Any algorithm, just as any population of organisms, evolves adaptation only to those inputs, variable or not, that it encounters. The only way to be sure of finding a global optimum is to test performance throughout the multidimensional adaptive landscape of possible structures. To assure finding this maximum, in the most general case, would require understanding the complete multidimensional structure and connections of the entire universe, down to the last quark. No advance in evolutionary computing, even as quantum computers increase the speed and breadth of learning or adapting, can guarantee discovery of a global maximum (Niu et al. 2019).

These problems in evolutionary computing have parallels in biological evolution. The generality and specialization of algorithms, we noted, can be probed by varying the environment. For natural populations, such probing of adaptations occurs when an environment varies in time. To acknowledge this variation, it has been suggested that a better metaphor is evolution in an “adaptive seascape.” Adaptations of organisms are thus like well-fitted algorithms, both of which perform well over a local optimum with a spectrum of periodicities in input. Yet they do not necessarily perform well in similar environments not previously experienced. Organisms, including human engineers, instead settle for adaptation to a (not too) local optimum.

Humans making decisions with the assistance of evolutionary computing have learned to extend the principles of natural selection. Making decisions based on trial and error, whether by brains alone or by brains assisted by machines, results in optimal responses to each of numerous inputs. It is the basic process of human behavior. Indeed all animals, not just humans, learn to match responses to inputs. Decisions occur whenever an organism discriminates between alternative inputs when choosing what to eat or where to go or whom to associate with or to imitate. They do so because decisions in response to unpredictable inputs allow greater specificity in adaptations. An organism’s capabilities and predispositions are specified by a stable plan, the organism’s genome. Such a plan, as discussed above, is the basis for all forms of learning and culture. This plan then develops in conjunction with its immediate context, the organism’s environment. Evolutionary computing is thus itself a result of evolution by natural selection.

Conclusion

Every organism develops from a particular plan in a particular environment. It persists as long as repair of its molecular components can counteract degradation – as long as its immediate structure can harvest exogenous energy to counteract entropy. Each organism, each instantiation of its plan, eventually decays. Yet, provided an organism transmits its original plan to nascent progeny, a similar organism in a similar environment can develop anew. Provided organisms transmit their plans to progeny with some appropriate level of variability, natural selection can yield a lineage of organisms that persists indefinitely in an environment of complex changes. Organisms with adaptations for learning can improve their survival in environments with short-term variation. These adaptations can extend even to learning the principles of natural selection. In the end, entropy, the ultimate noise in decisions, prevents learning with infallible foresight – and prevents immortality.

In a population of comparable entities, natural selection is no more than the spread of heritable

variants that replicate at a higher rate than others. Natural selection is arithmetic applied to differences. The principles are the same in all cases. The mechanisms of heredity vary across a spectrum of stability, from the relative inflexibility of the genome to the increasing flexibility of developmental switches, epigenesis, and learning, even to quantum computing. Each mechanism is optimized for a pertinent environment by selection itself. Natural selection is potentially constrained by interactions within and between the entities in a population. It leads to greater complexity whenever it can produce more precise and accurate adaptations. The scope of evolution by natural selection thus includes the evolution of culture, cognition, and language. It thus leads to brains so large that they strain the limits of skeletal adaptations. The scope enlarges still further to include even those decisions assisted by machines.

Finally, consider several misconceptions about natural selection. Each misconstrues issues addressed above. All contradict evidence or logic.

The first misconception claims that culture is distinct from biology and thus not subject to natural selection. On the contrary, environment and genome interact in the development of all organisms, including humans. All features of an organism, including their predispositions and capabilities for learning, are influenced by their genetic structure, just as all features of an organism are also influenced by their environmental context.

Another misconception is that natural selection cannot accommodate Lamarckian evolution, in other words inheritance of environmental influences on individuals. We now know that such environmental influences can affect progeny, but natural selection produces and regulates the necessary mechanisms for these influences.

A third misconception is that natural selection, inasmuch as it is a selection, implies the existence of a selecting agent. Darwin was aware of this difficulty with the term “selection.” Clearly rejecting any such agent, he nevertheless felt there was no succinct alternative for the term. Despite any limitations of language, there is no agent of selection.

Finally, it is sometimes claimed that selected individuals are morally superior. On the contrary, natural selection results from the arithmetic of survival and reproduction of genetic variants in limited populations. It has no more moral implications than any other example of arithmetic. Morality (ethics) instead applies to human attitudes toward the various consequences of natural selection. Because such behavioral dispositions are influenced by genes and by context, they are themselves influenced by natural selection.

Natural selection is not the child of morality; instead, morality is the child of natural selection. And not only morality but also philosophy. In the end, natural selection produces not only a philosophy of biology, but also a biology of philosophy.

Natural Versus Artificial Environments

Kevin Bennett

Department of Psychology, Pennsylvania State University, Beaver, Monaca, PA, USA

Introduction

Artificial environments first emerged from natural environments approximately 10,000 years ago with the advent of agriculture. Modern artificial environments differ in critical ways from the natural environments of our ancestral past, but psychological mechanisms shaped in our evolutionary past still help us navigate the social and physical complexities of the world today.

Natural Environments

For the first five million years of hominid history, our ancestors lived in small, nomadic bands of hunter-gatherers. On average, group size was likely maintained around 100–250 individuals. Based on correlations between primate brain size and social networks, Dunbar (1992) proposed that humans can comfortably maintain relationships with approximately 150 people. Because neocortex size effectively limits group size, many of our social adaptations are in tune with small cohesive groups with this capacity (Dunbar 1993).

The environment of evolutionary adaptedness (EEA) is the ancestral environment to which a species is adapted or the set of selection pressures that shaped an adaptation. A central premise of evolutionary science is that forces in our distant past helped make us who we are today. The EEA refers to a group of selection pressures occurring during an adaptation's period of evolution responsible for producing the adaptation (Tooby and Cosmides 1992). A selection pressure can be any factor in a population that impacts reproductive success. Physical, social, and intrapersonal pressures from our ancestral past help to shape our current human design because all animals have

heritable variations that are selectively favored or disfavored in accordance with reproductive success (Buss 1995). Each adaptation has its own EEA, or set of adaptive problems, that shaped it over evolutionary time.

The EEA does not exist as a single geographical location during a discrete period during human evolution. Rather it is a set of selection pressures that formed a given adaptation. For example, ancestral humans faced the adaptive problem of securing and digesting food to maximize energy. Taste buds were shaped in response to this adaptive problem. Our ancestors who showed a preference for salt, fat, and sugar were selectively favored over those individuals who did not have similar preferences. The acquisition of salt, fat, and sugar would have been challenging for our ancestors given the absence of agriculture and the inability to mass produce high concentrations of those items. The probability of survival and reproduction for individuals who showed a preference for those foods would have been greater than for those who did not. Our taste preferences were shaped in response to the problems posed by this environment.

Artificial Environments

Artificial environments first emerged from natural environments approximately 10,000 years ago with the advent of agriculture. The ability for human groups to maintain food and other resources in one geographic area for long periods of time ultimately gave rise to the first small communities, cities, and civilizations. The list of innovations that are present in the modern world but never existed in the EEA includes agriculture, electricity, refrigeration, large-scale weapons, medicines, mass communication, effective contraceptive devices, and virtually unlimited access to all types of proteins and carbohydrates.

The current population of the planet is considerably larger than at any other time in human history. Figure 1 provides some perspective on this time frame by graphically displaying the relevant recent explosion in world population. Our mental machinery, including emotions, decision-

Natural Versus Artificial Environments, Fig. 1 Graph of the global population from 10,000 BCE to 2020 CE, adapted from the US Census Bureau data. The graph shows very rapid growth since the eighteenth century. In the span of 40 years, from 1959 to 1999, the world population

doubled from 3 billion to 6 billion. According to US Census Bureau projections, the world total will reach 9 billion by 2042. (Source: U.S. Census Bureau, International Database, August 2016 Update)

making algorithms, and mate preferences, evolved under conditions that existed more than 10,000 years ago. Since the mid-1800s, the global population has increased tremendously – the blink of an eye on an evolutionary scale. These numbers dramatically illustrate just one of many features of our currently environment that is radically different from previous generations going back to the beginning of human history. Between 1959 and 2042, the world population will grow from 3 billion to an estimated 9 billion (US Census Bureau 2017). In contrast, the prior five million years of human history saw almost no significant population increases during any comparable span of time.

Interactions Between Natural and Artificial Environments

For many residents of urban areas around the world, cities represent the promise of a rewarding due to economic growth, developments in mass transit, and technological innovation. As a by-product of this progress, however, densely populated metropolitan landscapes pose unique psychological challenges not found in other environments. We are navigating our current social and physical world with psychological mechanisms designed to solve problems associated

with survival and reproduction in an ancestral environment much different than the one we live in now.

Websites and applications that enable users to create and share content (i.e., social media) illustrate quite nicely one of the greatest differences between natural and artificial environments. For the past five million years, humans faced problems posed by the social environment (e.g., decoding emotional expressions, communicating internal mental states to others, and detecting cheaters in social interactions, etc.). In response, natural selection shaped a psychological repertoire that includes mechanisms for solving face-to-face social problems. However, human communication has changed rapidly in short amount of time. We now use digital screens more than ever and, as a result, those finely tuned psychological adaptations are being used in a very different way, if they are being used at all.

Humans are particularly good at adapting to diverse surroundings. Harnessing solar power, working in high-rise offices, and navigating via global positioning systems are relatively new experiences that have been widely embraced. While artificial environments offer numerous benefits to health, longevity, and overall well-being, they can also result in unhealthy outcomes. A substantial body of interdisciplinary literature

has accumulated in recent years. Researchers in environmental science, urban planning, architecture, and landscape design have investigated the therapeutic effects of nature on children, adult stress levels in urban spaces, human performance in artificial settings, and criminality (Bennett et al. 2018).

There is now considerable evidence for the positive impact of plants, trees, and other sorts of greenery on physical and mental health. Modern technology, structural designs, and construction materials allows us to comfortably inhabit climates that would have required intense effort just a few generations ago. Still, we carry with us the psychological preferences shaped by generations of ancestors living in a much different world and often customize our environments to resemble that ancient habitat. Most of us prefer physical spaces that offer views of green vistas over windowless basements. Looking at trees might even have a tangible health benefit: Patients who viewed trees outside the window recovered more quickly from hospital stays (Ulrich 1984). Flowers also appear to have a positive impact on hospital patients. Bringing flowers increases optimism and improves the rate of recovery (Watson and Burlingame 1960).

Humans consistently prefer natural environments over built environments (Kaplan and Kaplan 1982). Using data from 30 studies, Kaplan (1992) summarized the results of participant ratings of photographed scenes of Western Australia, Egypt, Korea, British Columbia, and the United States. Across these varied geographic regions, participants preferred natural environments over built environments. Additional data suggest that the presence of trees and vegetation increases positive evaluations of built environments, thus demonstrating the transformative power of foliage (Ulrich 1983).

Other research has focused on the relationship between stress and uncultivated outdoor settings. When placed in uncertain and stressful situations, individuals who viewed pictures of nature scenery showed less physiological distress (Ulrich 1986). Contact with vegetation need not be active, such as gardening, to provide health benefits. Passively viewing vegetation through a window can produce desirable effects as well. Studies in biophilic

design demonstrate that people living and working in spaces with vegetation compared to those without vegetation show improved performance on mental tasks, more positive moods, greater ability to refocus attention, stress reduction, and diminished perceptions of pain in health-care settings (Kellert et al. 2008). Research looking at over 900,000 data points found that children who grew up with the lowest levels of green space had up to 55% higher risk of developing a psychiatric disorder (Engemann et al. 2019). The authors conclude that one long-term approach to improving mental health is to integrate natural environments into urban design.

Conclusion

Agriculture and modern city environments were nonexistent for 99% of human history, emerging only in the past 10,000 years. The modern industrialized world of today differs in many important ways from the natural environments of our ancestral past. This mismatch serves as a useful starting point for understanding the function and design of current psychological mechanisms. Because adaptations evolved over many generations, they are said to be “in tune” with reliable features of the natural environment. Still, we use those psychological mechanisms to navigate the social and physical complexities of the world today.

Synonyms

[Appeal to nature fallacy](#); [Argument from nature](#); [Is-ought problem](#); [Naturalism](#)

Definition

The *naturalistic fallacy*, as it is colloquially used, refers to the logical fallacy made when one derives moral prescriptions from naturally occurring phenomena or factual statements about the world.

Introduction

Moore (1903) coined the term the *naturalistic fallacy* to refer to instances in which one conflates morality with any other construct (e.g., pleasure, fulfillment, social good, God's will). Moore argued that, for instance, while morality and pleasure may both be used to describe a particular act, it does not follow that morality and pleasure are equivalent constructs. The modern usage of the *naturalistic fallacy*, however, most often refers to David Hume's is/ought fallacy, wherein Hume (1739) argues that statements regarding how things ought to be (i.e., moral statements) cannot exclusively be derived from how things are (i.e., factual statements). In other words, moral prescriptions cannot be derived solely from factual statements about the world.

Moral Prescriptions from Evolutionary Principles to Morality

An example of the *naturalistic fallacy* might include statements asserting the morality or utility

of Darwinian natural selection due to its existence in the natural world. Such erroneous reasoning led philosopher Herbert Spencer (1897) to advance a science-based morality in which he proposed that human welfare would be maximized by allowing the weak and poor to essentially die out while the “fittest” thrived in society (but see Wilson et al. 2003). Spencer’s (1897) philosophy was also based in a critical misunderstanding of natural selection, whereby he mistakenly assumed that evolution necessarily leads to human progress or advancement.

The *naturalistic fallacy* is commonly used to describe criticisms of evolutionary psychology that rest upon the notion that factual descriptions of naturally occurring behaviors are equivalent to moral prescriptions or justifications. For instance, critics accused Thornhill and Palmer (2000) of legitimizing rape as a moral behavior and blaming victims for its occurrence by studying rape as a naturally occurring phenomenon (e.g., Kimmel 2003; Rosser 2003; Shields and Steinke 2003). These allegations were made in error; it is not logically valid to claim that descriptions of rape as a natural behavior (i.e., occurring in nature) are equivalent to descriptions of rape as a moral behavior, and Thornhill and Palmer (2000) did not imply as much. Other critics, such as certain feminists, commit the *naturalistic fallacy* by wholly misperceiving the evolutionary investigation of human behavior as “a guide to moral behavior and policy agendas” (Nelkin 2000, p. 20), intended to legitimize and promote the subjugation of women (e.g., Kay 1990; Tang-Martinez 1997).

Conclusion

While the term “naturalistic fallacy” is frequently used in this way within the field of evolutionary psychology (i.e., conflating “is” with “ought”), Wilson et al. (2003) charge evolutionary theorists with misusing the term. Specifically, they assert that evolutionary psychologists inappropriately characterize the above criticisms of their field as

examples of the *naturalistic fallacy*. For example, Wilson et al. (2003) contend that Spencer (1897) was, in fact, not exclusively deriving “ought” from “is,” in line with Hume’s (1739) definition of the *naturalistic fallacy*. Rather, they argue that Spencer (1897) did not invoke “naturalness” in his argument’s factual premise to derive his ethical conclusion; instead, Spencer (1897) defended social practices that favored the strong and the wealthy because he believed that over time, they would produce a better society. Furthermore, Wilson et al. (2003) argue that evolutionary psychologists frequently fail to consider the full moral implications of their findings by neglecting to classify moral behaviors as products of natural selection. However, critics of evolutionary psychology who claim the field seeks to uphold social norms such as sex/gender-based inequality nevertheless misinterpret the intentions of researchers who utilize an evolutionary framework to study human psychology and behavior (i.e., who acknowledge that negative behaviors evolved in response to selection pressures and investigate the underlying causes of such evolved behaviors, but do not necessarily condone their use). Moreover, advances are being made in developing the evolutionary psychology of morality, which investigates the moral behaviors of human beings (see Shackelford and Hansen 2016).

Definition

Nature versus nurture is the debate regarding the influence of genetics/biology and environment on human development and behavioral characteristics.

Introduction

Are humans inherently good or bad and intelligent or unintelligent? Are humans born with certain traits, characteristics, and knowledge, or are these developed through experiences? These questions are at the center of the *nature* versus *nurture* debate, stemming back as far as 400 B.C.-E. *Nature* versus *nurture* is the dispute regarding the contributions of biological and environmental factors on human development. *Nature* encompasses genetic, biological, and hereditary factors that are innately present in humans, whereas *nurture* refers to those external, environmental factors that influence human development after conception, including childhood experiences and social relationships. Francis Galton, who coined the phrase *nature* versus *nurture* in 1874, said “Nature is all that a man brings with himself into the world; nurture is every influence from without that affects him after birth” (Galton 1874). Proponents of *nature’s* influence on human

development argue that individual differences are caused by genetic makeup and biology. On the other hand, supporters of *nurture's* influence contend that individual differences are the product of humans' experiences with the physical and social worlds.

Nature

Nature is considered to be humans' "pre-wiring" – the genetics and biology that are present from inception. The idea of nature being entirely responsible for human development and diversity was present as far back as 400 B.C.E. with philosophers such as Plato and Descartes, who proposed the idea that specific traits and characteristics of humans are innate and appear regardless of environmental influences. This idea laid the foundations for *Nativism*, which contends that humans' behaviors and characteristics are the product of genetics and heredity. Nativism segued into other intellectuals postulating on the influential role of inheritance and genes on development (Gordon and Slater 1998).

The struggle to understand heredity and how certain characteristics are shared between parents and offspring led many to speculate on the influence of genetics and evolution on human development. Francis Galton, who introduced the term *nature* versus *nurture*, proposed the idea that intelligence was almost entirely the result of inheritance, and argued that only intelligent people should be encouraged to reproduce, establishing the concept of *eugenics*, or the idea of controlling human reproduction with the intention of producing a "superior" race with desirable characteristics and traits. In 1866, Gregor Mendel published the *Theory of Heredity* and demonstrated how parents pass down traits to their offspring, providing strong support for the idea that much of human characteristics are the result of genetics (Lock and Palsson 2016).

In modern times, nature's influence on human development is still widely accepted and researched. Infants are believed to possess *core knowledge*, or knowledge about phenomena in the

world, such as objects, faces, and numbers, that is present from birth and could not be attributable to life experiences (Spelke 1998). In a study conducted by Pun et al. (2016), the researchers examined infants' perceptions of social dominance by presenting them with scenarios of members of different sized groups attempting to pass one another. In the study, infants looked longer at scenarios when a member of a numerically smaller group had the "right-of-way" over a member of a numerically larger group, indicating this event was unexpected for the infant. The results of this study demonstrated that infants possess elementary knowledge of social dominance by expecting that a member of a numerically larger group will have the "right-of-way" when in contact with a member of a numerically smaller group. Studies such as this provide support for the notion that humans are born with innate knowledge, likely resulting from evolution because of the importance of such knowledge for survival (Pun et al. 2016).

Nurture

Nurture refers to environmental influences on human behavior and development – it is the factors that are "external" to humans and occur after conception. Whereas the *nature* side of the debate was largely developed on the foundations of *nativism*, the *nurture* side was heavily influenced by *empiricism*. Empiricism asserts that learning and experiences are responsible for human behavior and characteristics (Gordon and Slater 1998). Several theories of human development and behavior have their roots in empiricism, such as John Locke's concept of *tabula rasa*. According to Locke, all human minds begin as a "blank slate," and that we learn and develop through our experiences and interactions with the environment. *Tabula rasa* maintains that there is no innate knowledge or characteristics humans are born with, but rather these are gained through life experiences.

Jean-Baptiste Lamarck's groundbreaking research on evolution provided support for the contention that the environment is a powerful

force in determining human characteristics. He proposed the notion that the environment can induce small changes in organisms, which are then inherited by subsequent generations and incorporated into their genetic makeup – this idea led to the *Theory of Inheritance of Acquired Characteristics*, first presented in 1801. Lamarck's theory demonstrated that the environment can have powerful implications for human development and biology (Lock and Palsson 2016).

In more recent times, a study of Romanian orphans has exhibited the undeniable influence of environment on human development and cognition. Researchers Sheridan et al. (2012) compared the brain structure and function of children in Romania who either had never been institutionalized in an orphanage, were once been institutionalized but had been placed in foster care, or were still currently institutionalized. The researchers found that children who had been institutionalized, regardless of whether they were eventually placed in foster care, showed significantly less gray matter in their brains than those who had never been institutionalized. Children who once had been institutionalized but now lived in foster care showed no significant differences in their cortical white matter compared to the children who were never institutionalized, but children who were institutionalized and did not move into foster care showed significantly less cortical white matter, demonstrating that being placed in foster care can improve white matter volume within the brain. This study provides conclusive evidence for the argument that environment plays a significant role in development, as being institutionalized as a child has been shown to have detrimental consequences for neural development (Sheridan et al. 2012).

Conclusion: Nature and Nurture

While genetics and heredity have been found to have a strong influence on the environment humans exist within, individuals' life experiences also determine how genes are expressed. Behavior and development seem to result from an

interaction of environmental and biological processes, and both are responsible for diversity among humans. Many phenomena can be explained in terms of both nature and nurture. Take the example of violence: while many scientists speculate that violence is a learned behavior that is observed from the environment and reproduced, it is equally possible that violence resulted from its evolutionary advantage for survival. Given that there is empirical evidence pointing to the influence of both nature and nurture on human development and characteristics, it is not a question of nature *or* nurture, but rather nature *and* nurture.

Nausea

Nicholas A. Davenport
University of Bath, Bath, UK

Synonyms

Biliousness; Feeling Sick; Queasiness

Definition

An uncomfortable sensation of an imminent need to vomit, usually perceived to originate from the stomach and occurring in waves.

Introduction

The term nausea stems from the Greek word “naus” (ship) and was originally used in reference to seasickness (Andrews and Sanger 2014). There are, however, a great variety of external and internal stimuli that can provoke nausea in addition to motion sickness. These range from alternate physiological sources, such as food poisoning or pregnancy, to psychological sources, such as anxiety. In terms of diagnosing the presence of nausea, there is a difficulty due to the lack of known biomarkers (biological indicators) of its presence. As a result, nausea can be challenging to detect without self-reports from the patient (Andrews and Sanger 2014).

Nausea is closely associated with emesis (vomiting) as it is often elicited beforehand. Some research suggests these two sensations utilize the same neural pathways and, as such, form a continuum whereby a nausea-evoking stimulus, when present to a larger degree, will trigger an emetic response (Andrews and Sanger 2014). However, this continuum model is contested, as it fails to account for scenarios whereby vomiting occurs in lieu of nausea, as seen in accounts of astronauts vomiting in space (Stern et al. 2011).

Effects on the Body

There are several alternate effects on the body that occur in combination with nausea. These include a rapid heart rate (tachycardia), sweating, blood vessel tightening (vasoconstriction), and yawning (Andrews and Sanger 2014). Additionally, stomach function has been demonstrated to decline while nauseated, which prevents or slows the toxic food from leaving the stomach to be absorbed into the body (Stern et al. 2011).

Toxin Ingestion

The primary adaptive function of nausea is considered to be the protection of the body from ingested pathogens and toxins, facilitating both immediate and future avoidance of the contaminated stimuli (Stern et al. 2011). Upon consumption of a pathogenic or toxic source, nausea serves as a warning signal to prevent any further ingestion. Concurrently, the progression of the digestive system is slowed to reduce the amount of the toxin that allowed to be absorbed by the body.

The function of nausea, however, extends beyond facilitating the immediate avoidance of the toxic stimuli by also promoting future aversion of the contaminated food, a process called taste aversion learning (Garcia et al. 1955). This form of classical conditioning forms a long-lasting association between the ingested food and the following nausea or further illness (Bayley et al. 2002). From an evolutionary stance, this adaptation facilitates survival through the promotion of future aversion to toxic substances which may otherwise be ingested recurrently.

The evidence for taste aversion learning primarily stems from animal research on rodents, most famously the experiments on rats by John Garcia. Rats are often used in research concerning nausea due to their lack of emetic reflex (they cannot vomit). As such, it is inferred that they rely on taste aversion to avoid consuming lethal doses of toxic food. Garcia et al. (1955) demonstrated the potency of taste aversion learning in a study into the effect of aversion resulting from gamma radiation. Rats typically prefer a solution

of water and saccharin, an artificial sweetener, over plain water; however, after the rats were conditioned to associate the solution with gamma radiation, the rats became aversive to the solution, preferring the plain water.

This taste aversion is specific to food consumption, as demonstrated by Garcia's later experiment with Koelling (1966). In this study, rats were given a water source which emitted an audio-visual stimulus (light and a clicking sound) as the rats consumed the water. When the rats were subject to an electric shock while drinking, the aversive reaction was directed towards the audio-visual stimulus – the rats associated the light and the clicking sound, not the water, with the shock. When the negative stimulus was replaced with an x-ray or a toxin, which elicit nausea in humans, the reaction of the rats was directed towards the water and not the audio-visual stimulus. This suggests that nausea as an adaptive function has evolved to reinforce the avoidance of ingested stimuli and, when there are multiple potential causes for the nausea, to direct the aversion to the ingested stimuli. This is further evidenced by nausea resulting from chemotherapy treatments for cancer patients. While the patients know that the nausea and vomiting are a consequence of the treatment they are receiving, they can still grow averse to the food they consume, associating it with the nausea (Garcia and Koelling 1966).

Pregnancy

A further adaptive function of nausea, interlinked with the ingestion of toxins, is “morning sickness” during pregnancy. This refers to the nausea and vomiting experienced by roughly 66 % of pregnant women that is most prevalent between the 8th and 12th week of pregnancy (Sherman and Flaxman 2002). Though not technically occurring more frequently in the mornings, this elicitation of nausea has the evolutionary function of protecting the mother and fetus from ingested toxins and pathogens. As aforementioned, nausea here also serves to prevent the ingestion of further amounts of consumed toxins and pathogens as well as to avoid the substance that hosted them

in the future. This can be seen in the cravings and commonly avoided foods during pregnancy. This idea has been encapsulated by the maternal and embryo protection hypothesis (Hook 1976; Profet 1992), which suggests that the primary toxins that are avoided during pregnancy are teratogens (chemicals that lead to birth defects) and abortifacients (chemicals leading to abortion of the fetus). Recent research has supported this assertion of aversion, specifically for pregnant women, towards strong-tasting vegetables and caffeinated drinks which host the chemicals. Flaxman and Sherman (2000), however, suggest that aversion to these chemicals were less common than aversions to meats, fish, poultry, and eggs. They go on to suggest that, from an evolutionary standpoint, this could be an adaptive response to the parasites and pathogens these foods can often contain. This would be especially critical for our evolutionary ancestors who were unable to preserve food for extended periods of time or, more recently, that heavily salted their meat which would also be dangerous for the fetus if consumed by the mother.

Motion Sickness

Motion sickness, at first glance, provides a challenge from an evolutionary perspective as there appears to be little adaptive value in nausea and vomiting as a result of motion. Additionally, it can occur in the absence of recently ingested food which would suggest that the immediate expulsion of toxins may not be the sole cause of nausea and that its etiology may be more complex. Treisman (1977), however, suggested that motion sickness is the result of inconsistencies in the spatial representation of at least one of three inputs: visual, vestibular (representation of the position of the head, primarily from the inner ear), and proprioceptive (position of the body, input received from the main body and limbs). Treisman argued that one or more of these inputs being discrepant is a signal of an ingested neurotoxin and, as such, nausea is triggered even in the absence of recently ingested food as a warning signal that a previously ingested food may be

altering the sensory inputs of the body. This theory has received little empirical support however, and the usefulness of regurgitating the remaining stomach contents after the toxins have already been absorbed would not rid the system of the toxins.

Conclusion

Nausea is an evolutionary adaption which has evolved to protect the individual from ingested toxins and pathogens. The immediate function of nausea is the prevention of consumption of further amounts of the toxic substance and to slow the digestive function of the stomach in order to limit the amount of toxins that are absorbed by the body. Furthermore, it serves to create an aversion to the substance containing the pathogen or toxin via taste aversive learning.

Navigating Social Relationships

April E. Zaragoza and Joseph A. Camilleri
Westfield State University, Westfield,
MA, USA

Error management theory (EMT) is a middle-level evolutionary psychological theory that helps explain whether people are more prone to making Type I errors (i.e., believe X when X is not true) or Type II errors (i.e., believe in Not X when X is true). Generally, the theory suggests that people may have evolved cognitive biases to make one type of error if it conferred reproductive benefits, or if it minimized costs of making the other type of error. For example, people are more prone to mistaking a stick for a snake instead of mistaking a snake for a stick because

there are harmful consequences for making the latter error (such as getting bitten by the snake and dying; Johnson et al. 2013). Though early applications of Error Management Theory were applied to explaining men's sexual over-perception bias and women's relationship commitment skepticism bias (Haselton and Buss 2000), this theoretical model is being applied to other domains, including navigating social relationships.

EMT has been applied to two areas social relationships that EMT. First is the *social exchange heuristic*, which refers to a cognitive bias towards cooperation (Yamagishi et al. 2007). Yamagishi et al. (2007) related the social exchange heuristic to concepts from EMT: a Type I Error is when a person thinks there will be a consequence but there is not (i.e., person cooperates when they could have defected without consequence), whereas a Type II Error is when a person thinks there will be no consequence but there is (i.e., person defects, but they were detected and incurred a punishment). EMT may help explain why people are more likely to cooperate in one-shot prisoner's dilemma game, because it may be more costly to defect and experience punishment/sanctions than making an error to cooperate when there would have been no consequence to defecting. This does not mean people will always choose to cooperate – social conditions that change the costs and/or benefits of cooperating or defecting may moderate such an effect. For example, if someone knows they are being watched, they are more likely to cooperate with others because there are more benefits for acting cooperatively and more consequences for not cooperating.

Error management has also been applied to explaining the *negativity bias* (Haselton and Galperin 2011), which is a tendency to believe that others are inherently bad if they committed bad behaviors. Attributions about negative traits after seeing someone act negatively can be wrong in one of two ways: Type I Error is incorrectly judging a person as inherently bad (i.e., believe actions were due to the person) when they are not, whereas a Type II Error is incorrectly judging a person as not inherently bad (actions were due to

the situation) when they are. The suggestion is that making a Type I Error in this case would not be as costly as making a Type II error, because avoiding someone who may not be harmful is not as bad as interacting with someone who is harmful, and so we may have evolved a tendency towards a negativity bias. The negativity bias is well supported in the empirical literature, though direct tests of its function as explained by error management theory are still needed.

Neanderthal Man

- *Homo neanderthalensis*

Neanderthals and Humans

Avantika Mainieri

Harvard University, Cambridge, MA, USA

Synonyms

[Archaic adaptive introgression](#); [Interbreeding](#)

Definition

Homo neanderthalensis interbred with modern humans 50,000 years ago. Approximately 2.5% of the DNA of many individuals living today came from Neanderthals.

Introduction

The only members of the *Homo* genus roaming the world today are humans, but 100,000 years ago *Homo sapiens* and *Homo neanderthalensis* were entwined in an interspecies love affair. Based on the perception of what Neanderthals supposedly looked like, with sloping foreheads, squashed noses, and a nasal voice, it is hard to believe modern humans ever found them alluring. But recent genetic evidence indicates that the two species did indeed fall in love and have fertile offspring. After a 4-year effort led by Svante Paabo and numerous research groups around the world, scientists published the complete Neanderthal genome in 2014 (Prüfer et al. 2014). Researchers compared it with contemporary human DNA and found that on average 2.5% of *H. sapiens* DNA is of Neanderthal origin. Because we all do not share the same genes, 20% of the Neanderthal genome can be found distributed in humans around the world today (Green et al. 2008). *H. neanderthalensis*, a population of humans who once ruled over Europe and Asia, went extinct around 40,000 years ago – but not before a little promiscuity that left foreign DNA in most of us years later.

Interactions with Modern Humans

Our *Homo sapiens* ancestors were never alone on the Earth. While we have been the singular species of the *Homo* genus for the past 10,000 years, the first humans evolved in East Africa approximately 2.5 million years ago. They were descendants of an earlier hominid called *Australopithecus*, who walked upright but had small brains (Their brains were not much larger than apes, usually 500 cc or less. In comparison, *Homo* brains are generally larger than 600 cc and modern humans average at 1350 cc.). Researchers have discovered as many as 27 unique human species, though paleoanthropologists still argue as to where to draw the line of speciation (Darwin was not the first but maybe the most well-known scientist who grappled with the definition of a species. He said, “I look at the term ‘species’ as one arbitrarily given, for the sake of convenience...” Years later Ernst Mayr introduced the biological species concept – species are groups of individuals that are reproductively compatible. However, this definition fails with all asexual organisms or populations that are only geographically isolated. While slightly embarrassing that scientists cannot agree on this basic concept, there are at least 20 valid published definitions and the debate does not appear to be slowing down. In light of current genetic data, some geneticists classify Neanderthals as a subspecies of humans). Some bands of these individuals left their homelands to travel north and settle in Northern Africa, Europe, and Asia. As different adaptations are needed to survive the cold forests in Siberia or hot temperatures of the Sahara Desert, human populations evolved and diversified. *H. neanderthalensis* lived and evolved in Europe for about 250,000 years before early *H. sapiens* moved into their lands (Higham et al. 2014). Our ancestors proliferated in their new environment, and the saga of the Neanderthals ended 10,000 years later when the species disappeared.

For decades, two competing theories were employed to explain the evolution of contemporary humans. One theory proposes that modern humans evolved in unison all over the world.

When *H. sapiens* moved into new lands, they bred with the early humans in Eurasia, and humanity evolved through recurrent gene flow (Wolpoff et al. 2000). In the alternative version, *H. sapiens* emigrated out of Africa and replaced all other hominins they encountered (Stringer 2003). In this tale of incompatibility and competition, *H. sapiens* had little sexual interest in other humans and wiped out all populations they encountered. The theory gained support in the 1980s after genetic studies revealed a recent origin of contemporary humans in Africa around 200,000 years ago (Allan Wilson, a geneticist at UC Berkeley, and his team used mitochondrial DNA to estimate how long human populations have been diverging from each other. All of the unique mitochondrial genomes today descended from a woman who lived in Africa around 200K years ago. Likening her to the first women from The Book of Genesis, scientists named her “mitochondrial Eve.”). Current information on the Neanderthal components in our genome suggests a third theory should be added to the mix: *H. sapiens* moved out of Africa around 100,000 years ago, and a few instances of interbreeding altered their genome. Though the receding chin and stocky frame of a Neanderthal may not be attractive to humans today, maybe being an individual adorned in feathers, with skin thicker than a rhino’s, was just the prettiest thing our ancestors had even seen.

DNA not only contains the blueprint for life but also a glimpse into the past. Frequently, certain populations of individuals around the globe will accumulate mutations in their genome. Most of these are neutral and cause no harm but can be used as markers for scientists to determine where and when a person’s ancestors came from. Based on the mutation rate in humans, interbreeding events took place around 50,000–60,000 years ago (Kuhlwilm et al. 2016). Whether these acts of copulation were clandestine meetings or commonplace is still a mystery, enough hybrid children were born within *H. sapiens* populations to allow Neanderthal alleles into the human gene pool. *H. sapiens* still living in Africa avoided meeting *H. neanderthalensis* and are the only individuals today without any foreign DNA in

their genomes. Contemporary East Asians inherited around 1.4% and Europeans about 1.2% of their genome from our hominin relatives. This Neanderthal DNA is clustered in our genome; some parts are bare, while other sections contain as much as 60% foreign genetic material (Vernot and Akey 2014). Like interbreeding that takes place in other vertebrates and plants, this hybridization happened in a patchy fashion. Advantageous *H. neanderthalensis* genes, like ones tied to the immune system, hair, and resilience for cold weather, survived through time and fixed themselves in our genome. Little Orphan Annie might have been singing a different tune if she knew that the freckles sprinkled on her nose are due to interbreeding – almost 70% of Europeans carry the Neanderthal version of a gene called BNC2 which influences skin pigmentation (Sankararaman et al. 2014). Fair skin and freckles helped *H. sapiens* efficiently synthesize vitamin D from low sunlight in northern latitudes.

Some Neanderthal-derived genes may have helped us in our evolutionary journey, but the vast majority were duds. When Paabo and his team were analyzing the *H. sapiens* genome for Neanderthal DNA, they found significantly less of it in functional versus nonfunctional parts of our genome (Prüfer et al. 2014). Only 1% of our DNA codes for proteins, and the majority of Neanderthal DNA is found in the spaces between our genes, where it has no biological effect. In the estimated 2,000 generations since modern humans and Neanderthals mated, natural selection has been hard at work, removing any of their deleterious alleles from our genome. The variants that escaped this purging also may not always have been a disadvantage. For example, Neanderthal DNA is linked with a blood clot disorder caused by the over-activation of the SLEP genes. In prehistoric times, wounds that closed quickly might have been advantageous when running away from a saber-toothed tiger but now can lead to strokes and heart attacks (Simonti et al. 2016).

Our current understanding of our distant relatives is that they were a sophisticated species who had large brains, used tools, and buried their dead. Scientists do not have a definitive reason for the

Neanderthals's extinction but do know that their entire population was struggling 40,000 years ago (Galván et al. 2014). Archaeological sites indicate that they lived in small bands and rarely interacted with people outside these troops. As men and women continued to mate with their relatives, deleterious genetic mutations remained in their gene pool, and the Neanderthals were reduced to low numbers. Traditional theories speculate that their small population was not able to compete with *H. sapiens* for resources, either through direct warfare or falling prey to evolutionary pressures from the changing climate. Whatever the reason, in the war between the two of human evolution, Neanderthals were cast as the losers, but not before their love affairs left their faint mark on our genome.

Conclusion

Homo neanderthalensis, called Neanderthals, walked the Earth around 200,000 to 30,000 years ago. They closely resembled *Homo sapiens*, though with a prominent brow, larger brain, and stockier build. Like other members from the *Homo* genus, they originated in Africa and migrated to Eurasia. Some scientists estimate that, at their peak, their population was as large as 70,000 individuals. In 2017, researchers found that modern human groups who originated outside of Africa contain around 2.5% Neanderthal DNA. This lends credence to the theory that humans and Neanderthals interbred and produced offspring. While the Neanderthals lived for several hundred thousand years, they died out about 30,000 years ago, from either warfare with modern humans, disease, or absorption into the larger human population.

Synonyms

Behavioral matching; Copying; Mimicry; New-born imitation; Selective imitation

Definition

The tendency for newborn infants to reproduce, imitate, or copy behaviors as they are modeled to them by an adult.

Introduction

Whether or not newborns have an ability to imitate has been the focus of considerable research effort over the past four decades. It has been considered a unique feature of the human mind and proposed to be the basis of later social-cognitive abilities (Lepage and Théoret 2007; Meltzoff and Williamson 2010; Trevarthen and Aitken 2001). There has, however, been mixed empirical evidence for its existence, placing neonatal imitation at the center of great debate with varied mechanisms and functions being proposed in an effort to explain the inconsistent findings. The most recent and comprehensive research on the topic suggests that there is no longer compelling evidence for neonatal imitation (Oostenbroek et al. 2016).

History of Neonatal Imitation Research

For the majority of the twentieth century, imitation was considered to develop between 8 and

12 months of age (Lewis 1936; Piaget 1945) and was viewed as evidence for the emergence of symbolic reasoning. Challenging this view, Meltzoff and Moore (1977) provided the first experimental documentation that newborn infants are capable of imitating both facial and manual gestures. Their study presented four gestures (tongue protrusion, mouth opening, lip protrusion, and sequential finger movement) to 18 newborn infants. Infants' responses were compared across targets (e.g., infant tongue protrusions when the adult models mouth opening), and it was found that neonates produced significantly more behaviors matching the target gesture when viewing that gesture, than when viewing nontarget gestures. Meltzoff and Moore interpreted this pattern of selective behavioral matching as evidence for neonatal imitation.

Replications and Subsequent Theories

Multiple studies have subsequently attempted to replicate and extend on Meltzoff and Moore's findings and have produced both positive (e.g., Field et al. 1982, 1983; Meltzoff and Moore 1989, 1992; Reissland 1988; Vinter 1986) and negative (e.g., Hayes and Watson 1981; Koepke et al. 1983; McKenzie and Over 1983; Oostenbroek et al. 2016) results. These inconsistent findings have led to a diverse array of proposed mechanisms for the phenomenon. A rich interpretation of these data (as favored by Meltzoff and Moore 1977) suggests that the matching behaviors seen in newborn infants indicate imitation in the truest sense. Alternatively, lean accounts instead propose that these behaviors are simply explained as either generalized arousal (Jones 1996) or the result of primitive reflexes (Anisfeld 1991).

Mechanisms of Imitation

Of the variety of theories detailing the mechanisms of neonatal imitation, five may be considered prominent.

Active Intermodal Mapping

Meltzoff and Moore (1994) describe the active intermodal mapping (AIM) hypothesis as a matching-to-target process that serves as a scaffold for understanding the intentional actions of others (Meltzoff and Moore 1992). Meltzoff and Moore refined the AIM hypothesis over several decades (Meltzoff and Moore 1983, 1989; Meltzoff 1985, 1990) and concluded that imitation is:

- (a) *Flexible*, displaying both variety and novelty
- (b) *Self-correcting*, with subsequent attempts improving in accuracy
- (c) *Specific* to the details of the modeled movements such as the duration and direction of the gesture
- (d) *Temporally flexible*, can be executed by memory after a delay and in the absence of any stimulus

Innate Releasing Mechanism

The innate releasing mechanism (IRM) theory posits that viewing certain stimulus configurations (e.g., an adult's protruding tongue) releases a pre-organized pattern of behavior resulting in the infant producing a behavioral match (e.g., protruding their own tongue). The IRM theory argues that matching behaviors seen in the newborn period are not "imitation" but rather an involuntary, reflexive triggering of a specific motor response that is released upon seeing a modeled gesture (Anisfeld 1991, 1996).

Arousal

The arousal hypothesis states that neonates are visually aroused and interested by the human face and find oral gestures particularly stimulating. Within this perspective infants explore a moving, or arousing, stimulus via increasing their own oral behavior. According to Jones (1996, 2006a), adult mouth and tongue movements are particularly interesting to newborn infants, and any match between the two behaviors is simply coincidental. The arousal hypothesis views other explanations of imitation as simply

misinterpreting infants' coincidental matching behaviors as evidence for true imitation.

Mirror Neuron System

Mirror neurons are activated both when an individual performs an action and when they see another executing the same action. These neurons were first discovered in the premotor cortex of macaque monkeys, and in recent years researchers have claimed evidence of neonatal imitation in macaques (Ferrari et al. 2006; Paukner et al. 2014; Rizzolatti et al. 1996). While these complementary strands of research are interesting, it is notable that monkeys are notoriously poor at imitating (Visalberghi and Fragaszy 2002). Moreover, while there is unequivocal evidence for mirror neurons in monkeys, there is very limited evidence for their existence in humans, let alone their attributed functions in human behavior. Thus as appealing as a proposal linking neonatal imitation and mirror neurons may be, the value accrued to it is unclear.

Associative Sequence Learning

The associative sequence learning (ASL) model suggests that the underlying capacity for imitation is not a specific or innate mechanism (as described by the above theories) but instead part of a general process of associative learning. It is common for parents to enthusiastically engage in imitative interactions, and parents regularly react with effusive positivity when their infant's behavior matches their own (Ray and Heyes 2011). However, according to the ASL model, although reward is not necessary to create sensory and motor associations, it dramatically enhances the rate of learning.

Functions of Imitation

Research has until recently been unable to provide satisfactory answers to whether imitation exists during the newborn period, and as a result there has been little empirical study on the functional relevance of newborn imitation. However,

some theories have been offered which view imitation as:

Communication

Meltzoff and Moore (e.g., 1994) argue that infants' imitation of others helps to establish rapport and identification of familiar people. They see imitation as a primitive means of establishing interpersonal communicative exchange via mutuality and reciprocity of matching the other's gestures.

Bonding

Bjorklund (1987) proposed that neonatal imitation is an adaptive mechanism that evolved to encourage social interaction between a neonate and an adult until the infant can intentionally influence social interactions. Proponents of this theory argue that early imitation elicits and maintains adult-infant social interactions, promoting caregiver attachment to the newborn.

Breastfeeding

Given that oral gestures are more likely to be imitated by newborn infants than any other gesture (Anisfeld 1996; Heimann et al. 1989), it has been suggested that the imitation of oral gestures may play a role in facilitating breastfeeding (Jacobson 1979). There are no published studies empirically evaluating this theory.

No Distinct Function

Finally, some researchers remain agnostic as to what function neonatal imitation might serve. Jones (2006a, b) has suggested that infants produce oral behaviors to explore their immediate environment. However, Jones highlights that this function may be a purely incidental to infants' production of gestures that happen to match an adult's behavior.

Is the Evidence for Neonatal Imitation Compelling?

In the last four decades, more than 80 published experiments have attempted to replicate Meltzoff and Moore's (1977) findings using the cross-

target procedure. Many have failed to find evidence of neonatal imitation (e.g., Anisfeld et al. 1979; Koepke et al. 1983; McKenzie and Over 1983). These inconsistent results and an inability to isolate the precise nature of imitation have led to many differing perspectives regarding its underlying mechanism and function. However, due to the inherent difficulties of infancy research and the relatively small sample sizes, it has been impossible to judge with certainty whether the positive or the negative results are reliable.

The largest longitudinal imitation study to date tested 106 infants at four different time points, 1, 3, 6, and 9 weeks of age, and found no evidence of selective imitation across the four time points (Oostenbroek et al. 2016). Infant responses to adults' modeling of facial gestures, hand movements, and vocalizations were recorded. Infants were just as likely to produce a nonmatching gesture when watching the adult model, as they were to produce a matching one. Regarding tongue protrusion, Oostenbroek et al. (2016) replicated previous studies in finding that approximately 50% of their sample produced tongue protrusions in response to the tongue protrusion model, but they found no sign of consistency across the infants' responses (i.e., infants who "imitated" tongue protrusion at 1-week-old did not consistently do the same at 3, 6, or 9 weeks of age). They argued that their results refute the view that imitation is an inborn ability and instead favor the traditional view that imitation is a skill acquired over the first several months of life.

Conclusion

After 40 years of debate, the best empirical evidence to date suggests that humans' imitative capacity is not inborn. Rather than casting imitation as an innate feature of the human mind, developmental scientists should now reconsider its origins and developmental trajectory and reassess theories regarding its functional significance in early infancy. This also motivates exploration of novel hypotheses about the functions of newborn oral behaviors (e.g., Keven and Akins 2016).

Definition

A fear of the unfamiliar. Food neophobia refers to the tendency to avoid eating unfamiliar foods.

Introduction

Food neophobia – a fear of eating unfamiliar foods – differs from picky eating or simply being a little fussy. Although there is evidence that these characteristics are correlated (Pelchat and Pliner 1986), neophobia serves as an evolutionary survival mechanism. Some mushrooms, for example, contain harmful toxins, so we are rightly cautious when we come across one in the wild. This initial neophobia could protect us from digesting a possibly lethal substance. In our current, food-saturated, and highly processed eating environment, it is perhaps difficult to imagine these sorts of life-or-death decisions having a great impact on us. However, they would have been very real problems for our ancestors. Through natural selection, then, these problems shaped the behavioral and cognitive mechanisms that underlie our eating behavior today. In the following discussion, to outline the evolutionary significance of neophobia, it will be considered in the context of (1) the Omnivore’s Dilemma,

(2) neophobic behaviors in infancy, and (3) the possible mediating role of disgust.

The Omnivore's Dilemma

The Omnivore's Dilemma (Pollan 2006) or Omnivore's Paradox, as it was initially described (Rozin 1976), refers to the conflict we omnivores face when deciding what to eat. On the one hand, we are *neophilic*, and crave variety, right down to our underlying metabolic processes. As Pollan describes, human metabolism requires Vitamin B12, sourced only from consuming animals, and Vitamin C, which we can only derive from plants. On the other hand, we are *neophobic*, instinctively worried about the unknown, and for good reason. Plants have evolved mechanisms to ward off predators, including producing harmful poisons and toxins. The evolved survival mechanism of neophobia is shared with rats too. In a now seminal paper, Paul Rozin (1976) demonstrated that when faced with a novel food item, rats sampled only a small amount, as a means of testing the dietary consequences of consuming it. In contrast, for specialized eaters such as koalas, no cognitive effort is required to assess the potential danger of a would-be consumed food item. They are hard-wired to treat eucalyptus leaves as food and anything else as nonfood. More complex processing is required in the digestive systems of these more specialized eaters, to derive the nutrients they need from their food source. There are evidently various solutions to the problem of food selection, which have evolved over evolutionary time. For omnivores, more complex cognitive processing (including neophobic reactions) allows us to navigate our food environment, while for more specialized eaters, the guts do the work.

Some of the cognitive processing that occurs to aid us in food selection is relatively low level. However, beyond early processing biases against bitter foods, or initial neophobia, for example, more complex processes have evolved. Notably, enhanced memory capacity, the ability to communicate and share information, and, more broadly, culture have all had an impact on the Omnivore's

Dilemma. As Pollan (2006) suggested, for non-specialist eaters with few constraints on food selection, "if nature won't draw a line around human appetite, culture must step in" (p. 298). Cuisine is one example of a cultural phenomenon that has altered our ability to overcome the Omnivore's Dilemma. This is the set of rules by which a culture prepares and eats food, including what is and is not safe to eat and what flavors and cooking practices are used to prepare food. In a sense, they are an "accumulated wisdom" about how to eat (Pollan 2006). Spices, for example, are used in many cultures to encourage familiarity with otherwise novel foods, working to reduce neophobia. The use of familiar flavors is also noted as important for reducing neophobic behaviors in children (Wardle and Cooke 2008). Thus low-level biases against bitter tastes, which can signal toxicity, work in concert with higher-level mechanisms including the ability to memorize and communicate what is safe, to help overcome the Omnivore's Dilemma, and ultimately to help us decide what to eat.

Infants and Neophobia

Neophobia works in conjunction with highly specified learning mechanisms to help infants navigate their food environment (Birch 1999). As Birch describes, one study from her research group found that neophobic reactions in two year olds do not go away through the repeated opportunity to smell or look at novel food; infants must be given the opportunity to taste the foods directly. This suggests that increased familiarity, which is well documented to enhance preferences in various domains (known as the "mere exposure effect"; Zajonc 1968), is not enough to reduce neophobia. What is important, however, is the ability to learn about the adaptive consequences of eating a novel food. There is some evidence that children prefer to eat food items separately rather than mixed together (Cashdan 1998), which is consistent with the idea that infants are "reviewing" the dietary consequences of novel foods. As described by Birch, this evidence is

consistent with the sorts of processes that are found in rats, who use learned safety as a mechanism in their food selection (e.g., Rozin 1976).

The ability to learn from others is also crucial in deciding what is safe to eat, and there is evidence that social facilitation reduces neophobia in infants. Again, the presence of food alone is not enough to encourage infants to eat, but watching an adult eat something increases the likelihood that an infant will do so also. Interestingly, there may be specificity in this social facilitation, and recent evidence demonstrated that infants learned the edibility of plants, but not artifacts, when watching these objects being placed into an adult's mouth (Wertz and Wynn 2014).

The timeline of neophobia in infants demonstrates a curvilinear relationship with age (Birch 1999). It is minimal in infancy; for example, infants who are just beginning to eat solid food need only a single positive experience with a novel food, to enhance their preference for it, and other similar foods (Birch et al. 1998). Parents also rate infants between 1 and 2 years as most receptive to new foods (Cashdan 1998). This is probably adaptive, as infants who are not yet able to forage for themselves should be fairly open to available food sources provided by their parent, to ensure nourishment. For children between 2 and 3 years, and to a lesser extent 3–4 years, parents report that children are less receptive to new foods (Cashdan 1998). Neophobia then generally decreases with age, as children and adults experience cuisine and learn the rules associated with eating, which can serve to reduce neophobia (as discussed previously).

Neophobia and Disgust

The emotion of disgust has likely evolved to help us to avoid harmful pathogens and parasites. It is possible, then, that disgust plays a role in neophobia, and this has been suggested by various authors in the field. Recent work by Al-Shawaf and colleagues has demonstrated a direct link between trait-level disgust and trait-level food neophobia (Al-Shawaf et al. 2015). Notably, those who were more neophobic had greater sexual- and

pathogen-disgust sensitivity. These researchers also found that males who exhibited higher preferences for short-term mating reported lower food neophobia (more openness to trying new foods). The authors proposed a preliminary hypothesis regarding these findings, suggesting that neophilia could be a form of mating display for short-term mating scenarios. They argue that if (1) a willingness to consume potentially pathogenic and harmful food is a sign of immunocompetence and (2) at least one factor that is considered in female mating decisions is immune health of the male (good genes) – especially in short-term mating contexts – then (3) neophilia (and a lack of disgust around new food) would serve as a mating display, an honest signal of good quality genes. This hypothesis is preliminary, and as the researchers note, more work is required. However, it certainly provides an interesting outlook on neophobic behaviors and evolutionary pressures that may underlie them.

Conclusion

The Omnivore's Dilemma sheds light on neophobia, and neophilia, and a number of other sensory and cognitive tools we have evolved to help solve the problem of eating. For infants, there is good evidence of specified mechanisms present from a young age, which enable them to navigate their food environment. This includes learning mechanisms that enable behavioral flexibility, including the ability to fully overcome their initial neophobia. It is likely that neophobia is related to the emotion of disgust, and preliminary evidence suggests a further relationship with mating strategy. Further research will continue to enhance our understanding of this fascinating phenomenon, and like with many other “quirks” of human behavior, evolutionary reasoning may prove to be an essential basis for this.

Nepotism

Nigel Nicholson
Organisational Behaviour, London Business
School, London, UK

Definition

Nepotism is the favoring of kin over nonkin in resource allocation, nurturing, or attention.

Introduction

At first sight, nepotism is quite obviously a product of evolutionary processes, by virtue of being an extension of genetic self-interest. As Forbes (2005, p. 83) puts it, paraphrasing Richard Dawkins: “Children are the vehicles that carry a parent’s genetic immortality.” The evolutionary origins of the word are visible in its ontogeny, a linguistic route from the mid-seventeenth century: *nipote* “nephew.” The Popes bestowed privileges on their “nephews” who in reality were more often than not their illegitimate sons. This perfectly illustrates the contemporary meaning in social life: patronage in public life on the basis of family relatedness. Some definitions include the favoring of friends, which shall be treated as a special case later in this entry.

Issues and Dilemmas

Yet there are potential conflicts of interest in nepotism, the primary one being the question of why should one bother being nepotistic when you can be purely selfish which is less uncertain in its benefits and less diluted by the genetic interests of other contributors to your progeny’s inheritance. The answer, of course, is that the nepotistic bias is essential for genes to persist – self-interest in one’s own fitness does not ensure the perpetuation of inheritance (Dawkins 1976). This is captured by the evolutionary concept of *reproductive fitness*, which W. D Hamilton demonstrated was embodied *kin selection*, the means by which we do this in infra-species interaction (Hamilton 1964). He extended the insight with the idea of *inclusive fitness* with which it is sometimes erroneously used synonymously. The nuanced difference between them is that kin selection denotes how your genetic interests are advanced by favoring your kin, while inclusive fitness spreads the web of interests more broadly over distant kin.

On the former topic, Hamilton predicted the degree to which we will favor kin by Hamilton’s Rule, $br - c > 0$ – where b is the beneficial on the fitness of the recipient of any social act, c is the cost to the benefactor, and r is the coefficient of

the genetic relatedness of two parties. This codifies an earlier mathematical formulation by Haldane and Fisher, which J.B.S. Haldane humorously captured by replying to the question, would you give your life to save a drowning brother, by saying he would save two brothers or eight cousins: the genetic break-even exchange.

In human tribal communities, scholars have documented numerous socially evolved adaptive norms and practice strategies that are sustained by the weak genetic ties that embrace the whole clan, by linking the strong ties prevailing among the tribe's constituent immediate kinship groups (Cronk and Gerkey 2007; Low 2007). These weak ties are reproduced by the near-universal norm of female-exogamy – young women marry out of their immediate kinship group into other clans, while young men remain importing daughters from other kinship groups. Thus, such generous practices toward nonkin as food-sharing and alloparenting (caring for others' offspring) are commonplace strategies that raise the fitness of the entire tribe (Hrdy 2009). This is reinforced by the human inability to detect relatedness instinctively and unerringly, unlike some other social species such as rodents that can do so by smell. Uncertainty about paternity is further reinforced by (a) the moderately polygynous instincts of our species and (b) the absence of manifest signaling of female estrus (Strassmann 1981). Male parental investment is especially necessary for neonatal survival during the early years of human life, hence uncertainty about paternity serves the group interest by supporting generous habits of social care in inclusive communities where individuals are at mainly related to each other only distantly (Buss 1996).

Hamilton's notable revision of evolutionary theory lies in framing inclusive fitness as the idea that one's genetic self-interest can be advanced without being a reproductive agent oneself. At a stroke this explains many puzzling phenomena, such as alloparenting, infanticide (selective investment in the most viable relatives), cannibalism (raising fitness), and homosexuality (able to foster fitness of kin by nonreproductive means). These phenomena are visible throughout the natural world; most extremely manifest in

what are called insect superorganisms. Among termites and wasp colonies, the queen fertilizing her own eggs to determine their sex results in very high degrees of genetic interrelatedness, such that nonreproducing members of the colony have the nepotistic incentive to engage in various self-sacrificial contributions to support the reproductive fitness of the superorganism, that is, the colony (Gillooly et al. 2010).

Nepotism in Human Society

Inclusive fitness strategies vary across societies. The phenomena discussed earlier – infanticide, adoption, homosexuality – have variously been discouraged or encouraged by cultural rules and norms (Faulkner and Schaller 2007). A multilevel selection view – sometimes crudely referred to as group selection – explains that such norms coevolve with changing material conditions and interests – what we may call the landscape of local ecology (Henrich 2004). This can be multilayered nested strata of a society, so that one can talk of a family, an organization, a social class, or ethnic community, to a nation state, as each having established ways or regulating their interactions to maximize collective fitness benefits. Within these, as the writer has argued elsewhere, much collaborative behavior with unrelated strangers operates on an “as if” principle (Nicholson 2000). We relate to strangers differentially and treat many of them with more trust than is rational. We treat strangers “as if” they were kin from our primal expectation that there is a correlation between relatedness, liking, familiarity, and similarity. This is an adaptive heuristic for the tribe in loosely related kinship groups where we have a common fate regardless of our degree of relatedness to individual members but leaves us vulnerable to being unpredictably cheated in the amorphous, transient, and uncertain networks of modern society.

However, we are highly interested in relatedness and act on the basis of our assumptions and knowledge of kinship. This shows that nepotism is moderated by cognition and judgment (Neyer and Lang 2003). To this we can add the

phenomenon, also present throughout many other species of birds and social animals, of favoritism. Parents especially enter into a calculus that leads them to favor the progeny whose fitness can be raised to the highest levels. Human mothers have been observed subconsciously give more nurturance to the most robust of preterm twins. There is also a substantial literature on how the risks of violent abuse by parents are many thousands of times raised when the victims are step-children (Daly and Wilson 1985).

Nepotism is fuel within the engine of families as political institutions (Bellow 2003), where there are continual contests of interests, shared and divided, including the incipient conflicts between parents and offspring and between siblings (Trivers 1974). Nowhere is this more visible than in the world of family business, where the politics of relatedness, favor, and divided interests continually threaten the stability of the governance of the business (Collin and Ahlberg 2012). Families regularly destroy businesses and vice versa. Yet, paradoxically, family firms frequently outperform their nonfamily counterparts, usually by virtue of their unique cultural strengths. Love is the emotional accompaniment of nepotism, and it hold families together and enables them to achieve superior forms of cooperation, innovation, flexibility, and problem-solving (Dyer 2006). To this extent, family firms could be said to succeed because they capitalize on their status as evolutionary primal forms of working and living together (Nicholson 2015).

Conclusion

Nepotism clearly plays a central role in adaptive evolution. In contemporary discourse about human societies, it is widely seen as pernicious by those who seek a rational rather than an emotional order to govern the ties of association and decision-making, yet we know (a) that the separation of reason and feeling is delusional ideal in human affairs and (b) that bonds of affinity and affection are the glue that hold families, communities, and societies together. If we recognize, absent of moralizing overtones, that nepotistic

impulses are an integral aspect of our common humanity, then it is possible and necessary to create the rational frameworks that ensure they do not corrupt those decisions in our societies that it is believed should be made by other criteria.

Definition

Research on language as a biological and neurological object

Introduction

The research area *neurobiology of language* aims to understand the genetic and neurological capacity that enables modern humans to acquire and use language. This language-related neurobiological capacity includes internalized syntactic, phonological, morphological, and semantic structures. Linguistic structures, which are externalized due to linguistic-cultural changes, are therefore not considered. Other relevant approaches comprise relevant genetic foundations, the examination of neural regions and circuits, and comparative studies mainly conducted with songbirds, cetaceans, and nonhuman primates. It is however controversially discussed *what* language is and *how* it might have emerged in the lineage of hominids.

Models and Paradigms

Charles Darwin's (1809–1882) work on natural selection and the evolution of organism represent the foundation for understanding cognitive capacities such as language in an evolutionary context. Already, in his remarkable volume *Descent of Man and Selection in Relation to Sex* Darwin

(1871) explicitly states that the human language system is an “instinctive tendency to acquire an art.” He regards language as a property of the human brain and considers birdsongs as a nearest analogy to the human language. He believes moreover that our ancestors may have used a musical protolanguage to express courtship and basic emotions. Darwin's view on evolution and language was way ahead of his time. He was however also attacked by linguists such as Müller (1866) stating that “language is the Rubicon, which divides man from beast, and no animal will ever cross it . . .” In the same year, the Linguistic Society of Paris even banned any debates on the evolution of modern humans. In the nineteenth century, Paul Broca (1824–1880) and Carl Wernicke (1848–1905) pioneered the field “neuropsychology of language” by discovering and modeling different types of aphasic disorders. Historical studies on language and related disorders were mainly concerned about describing and modeling these clinical disorders in relation to cortical lesions. Biological aspects of language such as the origin or evolution of the language capacity were mostly not considered.

In modern times, Eric Lenneberg (1921–1975) took up the questions about the human-specific biological capacity of language. Lenneberg (1967) argues that language is a species-specific trait, learning of this trait is not possible, and language is not an artifact of culture. He is particularly known for the hypothesis of a critical period for language acquisition. In this vein, Chomsky (1965) introduced in context of a nativist theory of language the concept of the *language acquisition device* and of the *universal grammar*, an innate human capacity to acquire language. He argues that toddlers acquire language reflex-like typically without explicit instructions, and despite of poverty of input and lack of negative evidence.

Today, most researchers agree that the human language is an innate capacity. It is controversially discussed however whether this language capacity evolved (e.g., Pinker and Bloom 1990) or is the result of a sudden mutation (e.g., Berwick and Chomsky 2016). This dispute mirrors to some extent the historical debate between Darwin and the scientific community, which defends a

saltationist view. Noam Chomsky argues that the human language faculty emerged by means of a sudden mutation in the last 50–100 ky. In contrast, others argue that language is the result of a gradual evolutionary process, which took place since the hominid lineage split from genus *Pan* 4–6 mya. Some argue that our closest biological ancestors employed a protolanguage (Bickerton 1981) and that already our sister species Neanderthals or Denisovans used language much like modern humans do (Dediu and Levinson 2013; Hillert 2015). Fossil findings but also limited genetic data provide indirect evidence about the evolutionary stages of language and the human mind. Since empirical data are mostly incomplete or missing, the debate is at present open and undecided.

More recent approaches try to understand the human language capacity in context of other cognitive capacities of the human mind. Numerous studies report comparable computations between the linguistic and other cognitive domains such as music or vision (e.g., Fadiga et al. 2009). The open question is thus whether the acquisition of language relies on a biological capacity, which is specific to language or to the human mind in general. A lion's share of attention received an article by Hauser et al. (2002), who consider the “narrow language faculty” as unique to modern humans, in particular with respect to its property of linguistic recursion. Originally evolved as an all-purpose computation, it refers to a computation, which calls itself such as it is the case when one sentence is embedded in another sentence. In contrast, the “broad language faculty” would share its properties with nonhuman animals. More recently, the operation (binary) Merge, which takes two syntactic objects A and B and forms a new object and which has also the property of recursion, is considered as the fundamental characteristic of language. The linguistic recursion hypothesis, which is part of the Chomsky's minimalist program, has been criticized for various reasons: nonhuman animals are able to discriminate recursive strings, phonological (non-syntactic) recursive structures can be found, some languages do not show evidence of recursive structures, and Merge and recursion can

be also found in nonlinguistic domains such as music (e.g., Corballis 2011).

Other approaches might also provide some clues how the human language capacity might have evolved. For different reasons, particular populations do not use a full grammar but seem to rely on a conceptual strategy to express their thoughts (Jackendoff 2002). Pidgin languages, for example, lack subclauses, grammatical words, and inflections. When a Pidgin language develops to a Creole language in the next generations, it becomes grammatically fully fledged (Bickerton 1981). Another well-known case is the “Idioma de Señas de Nicaragua.” Without the help of teacher or other types of instructions, deaf children developed their own sign language. First, they started to use pidgin-like home signs. Later, younger children modified this pidgin-like signs used by older children and added grammatical features much like when a Creole language emerges. Another example refers to agrammatism in Broca's aphasic patients, who suffer from lesions in Broca's area (pars operculus and pars triangularis) and surrounding areas in the left inferior frontal gyrus (IFG). These patients rely in production and comprehension on a basic subject-verb-object (SVO) strategy, avoid non-canonical sentence structures (e.g., *wh*-questions or sentences with relative clauses) and tend to drop grammatical words and inflections. It is an open question whether these and similar examples mirror an innate and hard-wired language capacity of our biological ancestors.

Our understanding of the neurobiology of language depends thus on the definition of language. The minimalistic program tries to specify the core property of language, that is, the ability to generate hierarchical internalized structures. It is claimed that this property is unique to humans and thus language would not have evolved but emerged when *H. sapiens* dispersed out of Africa about 75,000 ya. Others emphasize that the human language system is the product of a gradual evolution of different cognitive components and consider brain growth in the hominid lineage as an indicator of reorganization and new behavior. The gradual approach usually favors the assumption that the human language capacity

had a precursor in our biological ancestors. Since evidence about the possible evolution of the human language capacity is incomplete or missing, an inductive or empirical approach has at present its limitations.

Molecular Genetics

From a molecular viewpoint, the birth of a new life is a biochemical package, which includes information about development, regulation, and maintenance of cellular structures, which ultimately also determines the neural circuits scaffolding language processing. Our closest living relatives, the chimpanzees, share 96 % and Neanderthals 99.7 % base pairs with our DNA sequence. We might thus assume that Neanderthals' (or Denisovans') biological capacities for cognition were similar as compared to anatomical modern humans. Indirect evidence such as perforated and pigmented shells supports this hypothesis but any evidence about linguistic behavior is missing. DNA analysis shows that Neanderthals and *H. sapiens* diverged from the common ancestor *H. heidelbergensis* or *H. erectus* between 350–400 kya. Our estimates about the age of the language capacity is simply based on the fact about (a) the age of the Omo remains – the first discovered fossils of anatomical modern humans – and about (b) the time period between 50–100 kya when modern humans dispersed out of Africa.

No genetic data can be at present linked to the language capacity. Evidence has been found, however, that the forkhead box protein P2 (*FOXP2*) is expressed in different cortical areas including the basal ganglia and the IFG. Mutations of *FOXP2* in humans cause severe speech disorders and have been associated with verbal dyspraxia (e.g., Fisher et al. 1998). Members of the KE family suffer for three generations from a rare speech disorder while language comprehension seems to be preserved. Genetic analysis reveals that the found mutation was the result of an arginine-to-histidine substitution at position 553. R553H is part of the *FOXP2* transcription factor, represents a loss-of function mutation, and

is conserved in the KE family. Magnetic resonance imaging (MRI) shows that members of the KE family have a bilateral volume reduction of 25 % in the caudate nucleus and basal ganglia. These subcortical structures closely correlate with motor functions. Again, a reduction of gray matter was found in Broca's area, which might be related to the impaired cortico-basal ganglia circuits regulating control of articulation.

The human version of this gene differs from chimpanzees in two amino acid coding positions, which encode protein sequences. In this respect, modern humans and Neanderthals do not differ. We do not know however whether the speech-related mutations took place on these two protein coding regions. The noncoding regions of *FOXP2* seem to be different between Neanderthals and humans. Since the protein differences are minimal between humans and chimpanzees, the efforts focus on finding regulatory changes along with nonprotein coding differences. So far, it appears to be science fiction to establish a link between these findings and linguistic computations (or human cognition in general).

Numerous genes seemed to have contributed to the expansion of the neocortex in the hominid lineage. *SRGAP2* is of particular interest as the occurrence of particular hominids does not only correlate with copies of *SRGAP2*, which trigger brain growth and probably cortical reorganization, but also with the appearance of different artifacts (cf. Hillert 2014, 2015). Again, no conclusions can be drawn regarding the genetic foundation of language. A different approach to determine the role of genetics in brain development is to compare the cortical structures of monozygotic and dizygotic twin pairs. In one study an increasing similarity of brain structures has been found in subjects with an increasing genetic affinity (Thompson et al. 2001). The genetic factors showed a significant impact on Broca's and Wernicke's area as well as on frontal regions. Future studies may thus provide specific information about language-related genetic factors. They trigger the formation of particular neural structures, which in turn support particular linguistic structures such as the computation of inflectional morphology.

The brain of modern humans is highly efficient in terms of acquiring and computing language. Natural selection seems to have preserved the adaptive phenotype language and the brain has the plasticity to keep track of fast-changing linguistic information. It might have been a continuous evolving process, including genetic adaptation and the Baldwin effect, which led hard-wired linguistic computations.

Linguistic Microcircuits

An epigenetic model of language acquisition assumes that genetic expressions of neural growth interact with organism-specific experiences. In the case of humans, it has been argued that neural growth in the perinatal period involves the transition from gene expression to an *experience-expectant* phase, in which ubiquitous stimuli common to all members are required to modify the neural circuits. Neurons, which are in excess, are pruned and dendritic attrition shapes neural circuits. These circuits are thought to be relatively permanent, but can be used for subsequent neural sculpturing. Parameters are set for this critical or sensitive period phenomena. In contrast, during

the *experience-dependent* phase idiosyncratic information, which is unique to the individual, are stored. Thereby, active formation of new synaptic connections in response to the input will be stored. Both mechanisms apparently work against each other: stable and optimized neural circuits are the result of neural pruning and at the same time new neural circuits can be developed to assimilate new information. The formation of particular neural circuits for internalization of linguistic information such as phonology and syntax seems to follow a hardwired program, while other circuits are shaped by neural plasticity to cope for example with new lexical semantic information. For instance, the acquisition of canonical SVO (subject-verb-object) sentence structures can be directly mapped onto our sensory-motor experience. These structures might be acquired by experience-expectant processes, while more complex sentence structures may primarily involve experience-dependent processes. It remains to be seen whether this difference can be verified by the formation of different fiber track systems in young children.

Figure 1 compares language-relevant fiber streams in newborns and adults. The data are based on MR diffusion tensor imaging (DTI).

Neurobiology of Language,

Fig. 1 Fiber tracking in newborns (*above*) and adults (*below*) by using MR-DTI (Adapted and modified, Perani et al. 2011; © Proceedings National Academy of Sciences)

Newborns and adults have one dorsal and one ventral stream in common.

The ventral stream (green) connects the temporal lobe (TL) with the inferior frontal gyrus (IFG) via the extreme capsule (EC) and the dorsal stream (yellow) connects the TL with the pre-motor cortex via the arcuate fasciculus (AF) and the superior longitudinal fasciculus (SLF). In addition, children develop a second dorsal stream (purple: as shown for adults). This stream connects the TL with the IFG (including Broca's area) via the AF and the SLF.

At present, the core language model of an adult consists of a dual-stream system: The dorsal route maps auditory input to motor speech representations and the ventral route maps the auditory input to semantic representations. It has been suggested to divide the dorsal stream into an additional temporo-parietal-frontal segment. The anterior and posterior language areas are connected by means of a dorsal stream with the direct AF stream and the indirect MLF and SLF streams and by a multimodal ventral stream. Resting state functional connectivity (RSFC) in humans and autoradiographic data in monkeys suggest the following language-relevant circuits (see Fig. 2):

SLF connects the anterior supramarginal gyrus (aSMG; homolog in monkeys is PF, part of inferior parietal area) with the premotor Brodmann area (BA) 6, the posterior SMG (pSMG; homolog

is PFG, part of inferior parietal area) with BA 44 and the angular gyrus (Ang; homolog is PG, middle parietal area) with BA 45B and 45A; AF connects the superior temporal sulcus (STS) and the superior temporal gyrus STG with BA 44 and 45B; the middle longitudinal fasciculus (MLF) connects STS and STG with the pSMG and Ang; the ventral stream connects anterior parts of the STG, STS and MTG with Broca's area (BAs 44 & 45).

In particular, the dorsal stream seems to have undergone significant changes in the human evolution. They assume thus that the development of this auditory-vocal circuit was a key event for enabling modern language. Along with the acquisition of voluntary control over the larynx and the supralaryngeal tract by means of a direct projection to the brainstem, vocal motor neurons and the phonological loop with rehearsal operations may have emerged. Again, phonological computations may have contributed to the development of more complex syntax.

Functional MRI and diffusion tensor imaging (DTI) studies show that BA 44 is connected via the dorsal stream to STG/STS (Wernicke's area). Again, it has been assumed that the frontal operculum (BA 45 & 47) is connected to STG via a portion of the EC fiber system and the uncinate fasciculus of the ventral stream. Again, BA 6, which is part of the premotor cortex and

Neurobiology of Language,

Fig. 2 Fiber connections of language circuits based on RSFC in humans and autoradiographic data in monkeys (abbrev. see text; adapted and modified; © García et al. 2014; based on Kelly et al. 2010 © Federation of European Neuroscience Societies and Blackwell Publishing Ltd)

adjacent to BA 44, is mainly involved in orofacial muscular control and seems to be stronger connected to inferior part of the parietal lobe. In contrast, BA 44 connects to the posterior part of the parietal lobe. Similar, RSFC analysis indicates greater BA 45 connectivity to the Ang and to the superior and middle temporal gyrus (STG and MTG) relative to BA 44. This connectivity difference has also cytoarchitectonic reasons. Layer IV sends efferent fibers to the thalamus and has a reciprocal excitatory and inhibitory connection to the thalamus and adjacent areas. BA 45 is granular as it has a well-developed layer IV. BA 44 can be considered as dysgranular as layer IV is only rudimentary developed. BA 6 is agranular, that is, it is lacking layer IV of the cortical structure.

BA 44 seems to be critical for generating rapidly (100–200 ms) hierarchical syntactic structures as verified by early left anterior negativity found in event-related potential (ERP) studies. In contrast, BA 45 and 47 seems to be more involved in generating local phrase structures (Friederici 2009). Similar, it has been proposed that basic syntax (ventral stream) involves phrase structures, lexical retrieval and interpretation and extended syntax (dorsal stream) hierarchical, composed phrase structures, abstract rules and displacements (movements). Analogously basic (ventral) and extended (dorsal) computations were assumed with respect to the morphological and phonological level: Basic morphology requires the generation of whole words such as irregular, derived, or

high-frequent regular forms and extended morphology involves compositional structures as in the case of multimorphemic or regular forms. Again, basic phonology would consist of selecting discrete elements and retrieval of fixed lexical forms and extended phonology involves the composition of complex syllables and higher prosodic structures (Lely and Pinker 2014). Extended computations across all three linguistic levels would be scaffold by the AF, which connects the left IFG with the superior posterior temporal lobe regions. It is assumed that this dorsal route evolved more recently in the human lineage. Also, it has been argued that the extent to which fiber pathways are engaged depends on cognitive demand rather than on the type of linguistic information to be processed.

In addition, right-hemisphere functions such as prosody, intonation, and accentuation contribute as well to language processing in typical right-handers. Accordingly, it has been assumed that a right ventral stream integrates information over longer timescales while shorter timescales seem to be bilaterally represented (see Hickok and Poeppel 2007). Accordingly, the authors assume that during word recognition the left-sided sampling rate ranges between 25 and 50 Hz and the right-sided rate between 4 and 8 Hz. This model is based on the finding that rapid spectral changes such as formant transitions occur in a time window of 20–40 ms, while syllabic and prosodic structures are processed in the range 100–200 ms (Fig. 3).

Neurobiology of Language, Fig. 3 Dual stream model of speech processing (*p* posterior, *a* anterior, *d* dorsal, *mp* mid-post, *ITS* inferior temporal sulcus, *PM* premotor

cortex, *Spt* Sylvian parietal-temporal; other abbreviations used in text; adapted and modified, Hickok and Poeppel 2007; © Nature Publishing Group)

The finding that only severe speech perception disorders can be found if the patient suffers from bilateral (but not unilateral) lesions supports the idea of a bilateral ventral stream for speech. As already pointed out, the dorsal stream involves the posterior planum temporale, the premotor cortex as well as the IFG. The PT, which is typically larger in the left hemisphere as compared to Broca's area, is located posterior to the auditory cortex (Heschl's gyrus). It is the core of Wernicke's area as part of the STG and the parietal lobe. The PT is apparently involved in early auditory processing, in absolute pitch recognition (as found in music), but also in the analyses of many different types of sounds. Phonological information is mainly computed in the STS, whereas the interface of phonological-conceptual information is mainly recruited in the MTG and STG. Again, the anterior temporal lobe area computes semantic-syntactic information, which is basic according to the models mentioned above. The dorsal stream is responsible for auditory-motor integration. In addition to motor areas, STS and the Sylvian parietal-temporal region are involved in sensory-motor integration. Although top-down processing is not crucial for speech perception per se, it can facilitate speech recognition. The model discusses forward predictions: In the case of the ventral stream they are mediated by priming and context, and in the case of the dorsal stream by motor functions.

It is an extremely challenging research task to relate neuroanatomical structures to particular language functions. Future progress will strongly depend on the development of new techniques to examine noninvasively development and function of our cortical structure that enables us to acquire and generate sentences in a reflex-like manner. It is moreover extremely important to develop also appropriate theoretical frameworks to model and predict hardwired and internalized linguistic computations. Another important approach to be mentioned here in this brief review involves comparative studies.

Comparative Models

The study of cortical systems along with cognitive-behavioral patterns in nonhumans can

be relevant for understanding the human language system. This approach can provide valuable analogies how neurobiological circuits evolve and enable cognitive computations. Comparative studies focus in particular on our closest living relatives (great apes and monkeys) or on non-human vocal learners (e.g., songbirds and cetaceans).

The leftward asymmetry of Broca's area, in particular of BA 44, is not human-specific as this asymmetry can be also found in genus *Pan* (chimpanzees and bonobos) and gorillas. BA 44 seems to serve the coordination of gestures and vocalizations in great apes. It is possible that BA 45 expanded on the basis of BA 44 and increased cortical folding in the left IFG. The homolog of Wernicke's area is the left PT in genus *Pan*, which is much like in humans larger in the left hemisphere. Wernicke's area has been considered as an older cortical structure than Broca's area. The temporal-parietal region (Tpt) can be also found in some prosimians (e.g., lemurs and lorises). Macaque monkeys control their facial musculature by means of BA 44 and process meaningful vocalizations in the left hemisphere. The left superior temporal gyrus (STG) and the left inferior parietal lobe are homologs of Wernicke's area.

Based on findings with nonhuman primates, four different segments of the AF-SLF stream have been proposed: three SLF streams and the AF (Petrides and Pandya 2009). The SLF III stream has been in particular considered as a possible language stream as it connects the inferior parietal lobe with the homologs of BAs 44 and 45 (Broca's area). Several studies indicate however that in macaque monkeys the area Tpt (homolog to Wernicke's area) projects to the dorsal and lateral premotor area rather than to the language homologs 9/46d, 6d, and 8Ad. Again, significant differences of the neural pathways between humans, chimpanzees, and macaque monkeys revealed a comparative DTI study (see Fig. 4). In humans, the AF strongly connects in the left hemisphere the frontal lobe with the medial temporal gyrus (MTG) and the inferior temporal gyrus (ITG), including Wernicke's area. This region corresponds in macaque to the

Neurobiology of Language, Fig. 4 Schematic average tractographic results found for macaque monkeys, chimpanzees, and modern humans, (*IFS* inferior frontal sulcus, *IPS* intraparietal sulcus, *PrCS* precentral sulcus, *CS* central sulcus, *STS* superior temporal sulcus, *PS* principal sulcus,

AS arcuate sulcus (BAs in *red/orange*: Broca's area BAs 44 and 45 with extension BA 47; BAs in *blue/turquoise*: Wernicke's area BAs 22 and 40 with extension BA 37; adapted and modified, Rilling et al. 2008; © Nature Publishing Group)

extrastriate visual cortex, adjacent to the primary visual regions. The MTG and ITG enlarged disproportionately in the hominid lineage following the split from genus *Pan*. The pathways in

chimpanzees are slightly more developed as compared to those in macaque and may reflect some prior conditions that enable connections between meanings and motor sequences. However, it is

apparent that along with the increase of the human brain size the white-matter volume increased in frontal and temporal areas, in particular the dorsal stream.

Moreover, a unique set of neurons have been first discovered in macaque monkeys (Rizzolatti et al. 1996). They recorded single visuomotor neurons in the premotor cortex (area F5) of the macaque. The homolog of monkey's area F5 is ventral BA 6, which extends to BA 44 and the inferior parietal area in humans. These premotor neurons fired when the macaque performed an action (e.g., reaching for food). Some of the neurons fired as well as when the macaque observed a similar action by another monkey or by a human (e.g., picking up food). These neurons are called mirror neurons as they do only discharge when an action is performed or observed but not when an object is presented without an action. One-third of the F5 mirror neurons are classified as strictly congruent, that is, they discharge when observing and performing an action (motor encoding). Two-third of the F5 mirror neurons are defined as broadly congruent as they discharge when observing an action without motor encoding. When a macaque, moreover, hears the sound of an action typically associated with an object audiovisual mirror neurons fire in F5, but for most neurons the discharge is smaller for sound per se than for sound and vision. Also, F5 seems not to be exclusively related to manual tasks. For instance, in rhesus monkeys the cortical larynx representations overlap with F5 and BAs 12 & 45 are involved in vocalization. In sum, these single-cell recordings in primates revealed that some properties of mirror neurons are located in the premotor and parietal cortex.

More recently, the role of mirror neurons in the evolution of language has been more broadly discussed as action mirror neurons might have contributed to the evolution of spoken language (Arbib 2011). Accordingly, he divides between seven different evolutionary stages depending on each other. In particular, the evolution of complex vocalization does not need to depend strictly on gesture. It is also possible that the vocalization system coevolved with the gestural system. There is no specific reason to assume that

structures developed by the gestural system have been step-by-step transferred to the vocal system. Most of the communication in monkeys and apes is vocal (besides body language), and it is possible that auditory mirror neurons play a role in vocal imitation. Similar to a motor model for speech, vocal mirror neurons simulate the auditory input and can be therefore used to compare auditory input with own articulation. The basic vocal mirror neuron system may have become more complex by an increase of voluntary control of the vocalization mechanism. This has been probably accomplished by an increase of the auditory working memory in the prefrontal areas.

Research on the evolution of cortical circuits of vocal learning has been also performed with respect to speech and language in humans (Petkov and Jarvis 2012). The auditory pathway of vocal learners such as songbirds and humans was inherited from amniotes, which evolved during the Carboniferous period ca. 320 mya from amphibian reptiliomorphs and include today all reptiles, birds, and mammals. Vocal learning is a process that refers to the ability to acquire vocalization by imitation rather than by "instinct." Thus, a species can modify their vocalization patterns as a result of experience. It is apparent that vocal learning depends on auditory learning but auditory learning does not depend on vocal learning. Dogs, for example, can recognize spoken words but cannot vocalize them. Again, vocal learners must be able to use auditory percepts to correct their vocalization. The mammalian as well as the avian group have members, which can be considered as vocal nonlearners. More recent studies provide evidence that chimpanzees and other primates are also vocal learners but significantly less as for example songbirds. Thus, the capacity of vocal learning did not evolve from a common ancestor of both groups. Most interesting, the acquisition of human speech and of vocalization in songbirds appears to be comparable as both have sensitive periods before adulthood to acquire and maintain phonological or vocal sequences. Humans are highly prolific vocalizers by acquiring virtually infinite new phonological sequences during their complete life span. These sequences typically correspond to particular

meanings. In contrast, vocal learning in birds such as male zebra finch is hardly possible after puberty. Their songs have an emotionally rewarding experience such as mating or defending a territory.

In humans, vocal learning relies on pathway within the forebrain (prosencephalon). It consists of thalamic structures and the cerebrum (telencephalon), which includes the cerebral cortex and the basal ganglia. In contrast to vocal nonlearning birds, complex vocal learning birds such as songbird, hummingbirds, and parrots have particular forebrain neuron clusters (nuclei).

It is said that primates have an innate, involuntary vocalization system, which consists of connections from the amygdala, the orbitofrontal cortex (OFC), and the anterior cingulate cortex (ACC) to the periaqueductal grey (PAG) in the midbrain. Again, PAG neurons synapse to neurons of the reticular formation (RF); in turn, they synapse to the α -motoneurons in the nucleus ambiguus (Amb), which control the muscles of the larynx for vocal production. In nonhuman primates, BA 6 (area 6vr) projects in addition to the RF and from there to the Amb. Area 6vr and the ACC are also connected with the primary motor cortex, amygdala, and thalamic structures (not shown).

Humans rely more on the learned vocal pathway during speech. The learned vocal pathway projects from the face area of the primary motor cortex in BA 4 (laryngeal motor cortex, LMC) to the Amb (Fig. 5: red arrow) and a cortico-striatal-thalamic loop for learning vocalizations (white arrows). This matches in songbirds the direct forebrain projection to vocal motor neurons in the brainstem, that is, from robust nucleus of the arcopallium (RA) to the twelfth nerve nucleus (XIIIts). It has been stated that there is no direct cortico-bulbar projection in vocal nonlearners such as chickens and monkeys. In the case of a lesion in the LMC, learned vocalization is impaired in humans. Thus, it has been assumed that the humans' ability of speech and spoken language is related to the formation of a direct pathway from the LMC to the Amb. In general, studies with nonhuman primates were not able to report evidence for a direct pathway between

analogous areas of the LMC (e.g., 6vr) and Amb. A recent study with lab mice, however, might have revealed a region, which seems to be homologous: it is active during vocalization and makes a direct but sparse projection to the Amb (Arriaga et al. 2012). Connections between the anterior forebrain and the posterior vocal motor circuits are marked in Fig. 5 with dashed lines. Similar to humans, in mice two pathways converge on Amb, one from PAG and one from the primary motor cortex (M1).

According to new evidence that the vocalization system seems to be more flexible in modulating or mimicking sound patterns in species, which were assumed to be nonvocal learners such as mice and monkeys, a continuum hypothesis of vocal learning has been proposed. In general, auditory processing can be easier modeled in non-human animals compared to learned vocal communication. However, not all patterns of human speech can be modeled in animals and not all vocalization patterns in animals can be modeled in humans. Since a certain group of songbirds and humans are excellent vocal learners, the question arise to what extent human sentences and bird songs can be compared at the syntactic level.

First, human language consists of a lexicon and syntactic rules. This lexical-syntactic system externally interfaces phonological and phonetic information in perception and production and internally it interfaces semantics including concepts, intentions, and emotions. Typically, bird-songs do not express abstract meanings, if at all some intentional or emotive states such as the attempt to attract mates or to defend territories. Thus, we may say that birds (or typically animals in general) use pragmatic meanings rather than semantic meanings. Again, birds make use of a phonetic syntax rather than of phonological syntax as the term phonology refers to the mental representation of an abstract sound system to convey meanings. In contrast to birdsongs and to animal communication systems in general, human language uses discrete semantic units and morphosyntactic rules to combine and create open-ended variations of new meanings.

Birdsongs use variations at the phonetic level but obviously not at the semantic level. For

Neurobiology of Language, Fig. 5 Schematic illustration of the vocal subsystems in (a) humans, (b) macaques, (c) mice, (d) songbirds, and (e) chickens: *ADSt* anterior dorsal striatum, *Amb* nucleus ambiguus, *Area 6/V* ventral part of Area 6 premotor cortex, *Area X* a song nucleus of the striatum, *ASst* anterior striatum, *AT* anterior thalamus, *DLM* dorsolateral nucleus of the mesencephalon, *DM* dorsal medial nucleus of the midbrain, *H* hindbrain, *HVC* hippocampus, *LMAN* lateral magnocellular nucleus of the anterior nidopallium, *LMC* (*BA 4*) laryngeal motor cortex, *M* midbrain, *M1* primary motor cortex, *M2* secondary motor cortex, *nXIIIs* 12th tracheosyringeal motor neurons, *PAG* periaqueductal grey, *RA* robust nucleus of the arcopallium, *RF* reticular formation, *T* thalamus, *VL* ventral lateral nucleus of the thalamus (Adapted and modified, © Arriaga et al. 2012; see Petkov and Jarvis 2012)

instance, a nightingale can rearrange clusters that generate hundreds of different songs. They may be used for identifying individual birds and express the level of sexual arousal. Canaries use sexy syllables to increase mate attractions, but this does not change the meaning of the song and indicates only the motivation level. Again, humans are able to synchronize the speech-meaning dimension with physical movements (dancing and acting) and/or complex music patterns (beat and harmonics) for a high-coordinated meaningful and/or pleasurable performance. Since a behavioral comparison is not possible at the semantic level, to what extent is the song-syntax of songbirds comparable with the human sentence-syntax?

Human language consists of nonlinear relationships between words. For instance, in the sentence *The guitarist, who plays Bossa Nova, went on stage*, the noun phrase (NP) *the guitarist* has to be linked to the verb phrase (VP) *went on stage* to understand the sentence meaning, that is, it is the guitarist, who went on stage. These kinds of nonlinear links are called nonadjacent dependencies, which are inherently part of the hierarchically organized structure of syntax in human languages. Moreover, nonadjacent dependencies are systematically ordered and require simultaneous processing of different structures to link these codependencies. Our nonadjacent dependency example above involves a nested center-embedded dependency, which are generally called as being recursive. The dependencies are embedded within one another as in the structure $a^1a^2a^3b^3b^2b^1 \dots a^{n-1}b^{n-1}$, whereas a^{n-1} is the unit to be linked to b^{n-1} . In contrast to this context-free grammar version, a finite-state form has the structure $a^1b^1a^2b^2a^3b^3 \dots (ab)^{n-1}$, in which iterations are appended to the end of a pair (Berwick et al. 2011).

In examining acoustic pattern recognition in European starlings evaluated the syntactic recursion hypothesis that the capacity of self-embedding is unique to the human language faculty (see Fig. 6). They conclude that the use of syntactic recursion is not unique to humans as their trained starlings have shown the ability to recognize these recursive patterns.

Berwick and colleagues (2011) emphasize however that the patterns tested do not match those sentence structures used by humans. While European starlings seemed to be able to recognize nesting after training, which needs to be differentiated from natural settings, they did not provide evidence of the bird's ability to recognize dependencies of the kind that pairs specific a 's with specific b 's. The starlings tested above recognized an equal number of a 's and b 's in terms of rattle and warble sound classes (rattle3warble3 patterns), but it has not been examined whether these rattle-warble patterns were properly paired off. Thus, at this point there is lack of evidence that songbirds or any other nonhuman species are able to use a strict context-free grammar. Birdsongs seem not to be able to generate hierarchical structures, which is one basic principle of human syntax.

For example, acoustic features of rattle or warble are not used to classify the rattle-warble sequence as a new unit, which in turn could be then used in more complex structures. Some songbirds however such as Bengalese finches seem to be able to perceive 3–4 notes as a single unit. In one study, the method of the classical psycholinguistic click experiment was applied, in which human subjects were presented with a click in the middle of a phrase (e.g., *ate the apple*). The participants tend to report that the click occurred at the beginning or end of the phrase. In using this click protocol, the authors reported that the Bengalese finches responded in a similar fashion: They perceived the click at the c or e of a cde unit. The Bengalese finches do not only perceive such units but can also produce them. Thus, it appears that they are able to combine notes into units much like humans use words to combine them to noun or verb phrases and to use these units somewhere else. However, in contrast to human syntax, Bengalese finches seem to lack the ability of dependent nesting to manipulate these combined notes. In this vein, it has been demonstrated that cotton-top tamarins (*Saguinus oedipus*) are able to parse synthetic stimuli sequences generated by finite-state grammars, but not those generated by a phrase structure that implies a simple recursively hierarchical structure. It is characteristic for human syntax that not

Neurobiology of Language, Fig. 6 Conditioned European starlings' sonograms of (a) rattle-warble iterations and (b) rattle-warble nesting (Adapted and modified, Gentner et al. 2006 © Nature Publishing Group)

a specific order of individual words is acquired but the specific order of word classes, also called phrase structures. Each single word can be inserted into a syntactic structure that provides a placeholder for this particular word class.

Also, new words can be created or different noncompositional strategies can be used to express figurative meanings. In the case of idioms, for instance, a sequence of different word classes can be treated as a unit that the syntactic structure does not map onto the compositional semantic structure. To understand the meaning of *It rains*

cats and dogs, the phrase needs to be processed as a single unit, as a string of words, and excludes combinatory computations between the individual words. Such kind of linguistic parsing flexibility to express nuances of different meanings seems to be unique to humans.

Conclusion

In context of this brief overview of the field *neurobiology of language*, we were constrained to

focus on the mainstream issues currently discussed. Thus, many important aspects and contributions to the field could not be considered here. In principle, all scientific approaches may provide useful insights about the fundamentals of mind and language. In this vein, humanities, social sciences, and life sciences seem to come closer in the attempt to map linguistic models to neurobiological capacities (and vice versa). It is obvious that this research agenda requires further specializations to accommodate cross-fertilization between established scientific programs. Here, not only the development and use of new technologies are of great significance but also theorizing is most important in terms of methodology and predictions. Advancing the research at both ends is essential for improving our understanding of language as a biological system.

Definition

Neuroethics is a relatively new field that covers topics concerning the social, legal, and ethical implications of neuroscience and addresses aspects of neuroscientific research.

Introduction

The field of neuroethics has been addressing issues of neuroscientific research for many years. In the past, many controversial topics have been researched; for example, in the early 1940s, pre-frontal lobotomies were used to treat mental disorders. This procedure involved severing the frontal lobe from the rest of the brain in an attempt to ease symptoms, such as suicidal ideation, obsessions, and delusions. Experimentation during the 1930s and 1940s led to the infamous Nuremberg trials where criminals from the Nazi regime were punished for their crimes against humanity. Among other atrocities, their crimes included neurosurgical procedures such as lobotomies, experimentation on human participants without their consent, and other inhumane experiments. Following this, many boards were formed over the next 30 years, including the International Brain Research Organization and the Society for Neuroscience. These organizations review how research is conducted and how neuroscience is taught to students.

The ethical implications of neuroscience, such as the privacy of a participant's brain scan, can ripple through other aspects of neuroethics, such as its social and legal aspects. If, for example, a participant's information was to be identified, due to the small sample size of neuroscientific studies, the social ramifications could include future discrimination if said participant had a deviance from neurotypical brain scans. Although this could be a very small difference in the brain, the general public may believe it to have a larger impact. Indeed, many people deem information and studies concerning the brain to be more accurate and important (Farah 2005). This misunderstanding could also influence the legal side of neuroethics. For

example, brain scans could be given as evidence in a court system that does not fully understand how to interpret these data. This could lead to swaying a jury, wrongful convictions, and weakening the system that is currently in place, depending on how much the general public values neural data. The three main sections of neuroethics (ethical, social, and legal) are crucial in maintaining a safe practice of research that not only protects the participants but also the researchers that embark on attempting to understand and further science.

Ethical Implications of Neuroscientific Research

If we were to use modern ethic boards and regulations, previous work deemed well-intentioned by the researchers themselves and, commonly, others would fall short of the ethical standards we hold today (Illes and Bird 2006). Neuroethical researchers have attempted to identify the major ethical dilemmas that past and current researchers face. Privacy is a major concern among researchers in this field. A participant's privacy encompasses all information collected from them, including brain images, test scores, and unique identifiers. These data, particularly their unique and limited brain scans, may be more identifying than data collected for other psychological or biological purposes (Illes and Racine 2005).

Another argument under the privacy umbrella is whether to allow researchers to gather information about intimate details of a person's life. Many people speculate that as technology advances, data may be able to estimate what people are thinking (Illes and Racine 2005). The main concern is that these thoughts will not be private and can then be shared among researchers (Illes and Bird 2006). Commonly, the thought of someone being able to read another person's mind is intrusive and scary, so exploration of this topic would be no different. Similarly, understanding what and why people think the way they do is a very appealing strategy for marketing research. The

term "neuromarketing" describes companies using neurological methods to understand how participants react to their marketing materials. The information that is gathered from studies that either appeal to or are conducted by these companies is at risk for being more popularized and, therefore, more susceptible to identification (Farah 2005).

Social Implication of Neuroscientific Research

Neuroscientific research can be arduous to understand even for trained researchers. The general public is poised at a disadvantage because they are not educated in how to properly read and interpret this difficult information; for example, many individuals have heard of magnetic resonance imaging (MRI), but cannot describe how it works, what it measures, or interpret the information that it provides. Advanced technology is commonly used in neuroscientific research, which can enhance the amount of confusion for a layperson trying to understand the data. Neuroethics aims to focus on the social implications that this type of research can have, especially when misunderstood.

Because confusion can stem from limited scientific training or expertise, dissemination is one of the main concerns facing neuroethical researchers. If the average person does not understand a study's findings, but deems them more definite and accurate (Farah 2005), the misunderstanding could be dangerous. Similarly, studies that include brain images have been rated higher in their scientific reasoning as opposed to studies shown with bar graphs, a topographical map of the brain, or no image (McCabe and Castel 2008). Neuroscientific research garners a considerable amount of media attention, and when not properly disseminated can enhance the likelihood of a misunderstanding. This can lead to neuro-determinism, as individuals manifest this belief in neurological data being concrete and accurate. An individual that falls into this category would put more trust into neurological data. This can become increasingly problematic if this level of trust influences the individual to develop

prejudices. For example, if a brain scan was identified, a potential employer may not hire an applicant if they perceive any so-called anomalies on the scan. Even if they were benign in nature, a layperson may not understand that these anomalies would have no effect on behavior, yet their prejudices could lead them to treat the individual differently.

Similarly, the field of neuromarketing grows as an increasing number of companies believe it to be the future of business (Ariely and Berns 2010). This new area will potentially allow marketers to understand a consumer's desire more fully than when they are asked how they feel about a product. Although this domain is still open-ended and largely uncharted, the standards concerning research and ethical codes that these companies uphold are vastly different from a typical experimental setting (Murphy et al. 2008). Even though government, academic, and some commercial settings are required to obtain informed consent and protect the participants' privacy, these requirements are missing when the participant is tapped for a neuromarketing study. The research that is conducted in more privatized and commercialized settings are not required to follow the same guidelines, which can influence the ethical integrity of the research itself.

Legal Implications of Neuroscientific Research

Similar to the social effects of neuroscientific research, data that are difficult to interpret can affect the legal system. New studies have proposed using neuroimaging as a way to detect lying, by viewing specific areas of the brain, including the anterior prefrontal cortices, the parahippocampal gyrus, the right precuneus, and the left cerebellum (Ganis et al. 2003). One study reported a 90% success rate at differentiating deceptions during a test for participants that were asked to lie about an object they were asked to take (Kozel et al. 2005). Although the deceptions in this test were very straightforward, many researchers have called into question the extent that this would be a successful measure for more "real-world" data (Illes

and Bird 2006). Similarly, "brain fingerprinting" uses event-related potentials that are measured with electroencephalographical methods. These tests have been used to identify "guilty knowledge." For example, a participant may be shown information that would only be relevant for an extremist group that they potentially belong to; if this participant displayed an increased amount of activity at the sight of this information, it would be considered guilty knowledge, due to them understanding the significance of the stimulus (Farah 2005). This test has been thought of as a way to determine whether perpetrators have more information on the associated stimulus than they want to disclose, such as would be the case with terrorists and criminals. Although these data can be portrayed as alluring, many neuroethical researchers are concerned with this being heralded as the new polygraph test, which has been shown to be widely inaccurate, especially when participants are privy to counteractions such as biting their tongue or counting backward from a specific number to calm themselves (Honts and Kircher 1994). Because these new measures hold the power to become the new polygraph, it is important to ensure that the public understands the data that are the basis for using any kind of lie detecting test. Similar to the social aspects of dissemination being so important, it is crucial that the legal system recognizes the details of these tests. For instance, if neuroimaging is used, the studies that have been previously conducted have not supported "real-life" deceptions, so this particular test would be of no use in a legal case.

Neuroscientific research also has the ability to undermine the idea of free will by suggesting that humans are nothing more than the product of their anatomical makeup. Although most research would not suggest such a strong declaration, many people may mistakenly advocate that criminals have no choice in their actions due to how their brains send signals to commit an action (Farah 2005). Similar to a reflex, the brain may react a certain way that opens the discussion for whether the human mind can control how they respond to a situation before the physical brain makes them do something else. This could lead to more lenient penalties for criminals, especially those in situations that warrant a reflex or instinct, such as

accidentally wounding a police officer when they felt threatened.

Conclusion

Neuroethics encompasses the ethical, social, and legal aspects of neuroscientific research. Each of these aspects has concerns about how research may affect the public. As discussed, the ethical implications of this type of research are primarily related to privacy. Participants are entitled to assurance that the information they willingly give will remain confidential. Because studies in this field have such small sample sizes, it is more likely that information could be identifying. Similarly, the social aspects of neuroethics are primarily concerned with dissemination and understanding of research findings. If the general public struggles to understand a study, but is able to identify one or more of the participants, this could lead to discrimination, privacy violation, and an overall misunderstanding. The way that research is distributed to the public is crucial to how people may view it; people may view neuroscientific research as more important, but may not be as enticed by other fields of study. Because of this, the legal system can also be affected. Recent work has shown successful deception detection; however, researchers have not investigated complex forms of deception. The general public may also take findings at face value, especially when shown reports of 90% accuracy. Without proper dissemination and explanation, this could become a new form of lie detection that is not as accurate as people believe it to be, similar to the polygraph. The ethical, social, and legal aspects of neuroethics each hold numerous concerns that should be addressed when researchers consider conducting and publishing their work.

Definition

Humor is anything that is perceived as funny and makes people laugh.

Introduction

Humor is a heterogeneous concept. There is currently no consensus on how to best define humor, but according to one prominent cognitive account it is a complex experience, which involves detection and resolution of incongruity, followed by the feeling of amusement and laughter. It also refers to creating and expressing something funny. Abnormal humor is characteristic of certain neurological conditions, where specific humor-related deficits depend on the type of condition. The deficits may range from a partial or total inability to comprehend or appreciate humor, to those related to humor production, as reflected in a compulsive need to make disinhibited, often inappropriate jokes. Furthermore, some neurological conditions are characterized by pathological laughter, i.e., inappropriate and uncontrollable laughing, which may or may not be associated with the feeling of mirth.

Defining Humor

Humor is a universal human experience. Even though we can easily recognize humor when we experience it, there is no consensus on how to best define it. This broad term refers to the experiences of perceiving and appreciating something as funny as well as creating and expressing something funny. The complex nature of humor is reflected in the fact that it involves multiple processes, with some types of humor (e.g., comics, strips, cartoons, semantic jokes, etc.) requiring high-order cognition, such as theory of mind (Vrticka et al. [2013a](#)). Also known as mindreading, theory of mind is the ability to understand and predict mental states (e.g., beliefs, desires, intentions, emotions, etc.), one's own as well as those of others (Apperly [2011](#)). Theories of humor processing differentiate between humor detection, i.e., "getting the joke" and humor appreciation, i.e., "enjoying the joke." The former is a cognitive component of humor processing, which is associated with attempts to reconcile disparities between the punch line and the expectations based in the storyline. The latter is an affective component of humor processing, which is associated with the emotional responses caused by the experience (Manfredi et al. [2014](#)). The positive emotional response to humor is referred to as mirth, exhilaration, and amusement, which are used interchangeably in the humor literature. Thus, humor requires comprehension processes (the cognitive component); once detected, it is typically associated with amusement or the feeling of mirth (the emotional component) as well as with laughter (the motor component). Darwin captured the link between humor and laughter in the "tickling of the mind" analogy: "The imagination is sometimes said to be tickled by a ludicrous idea; and this so-called tickling of the mind is curiously analogous with that of the body" (Darwin [1872](#), p. 201).

Experiencing something as funny has evolutionary significance. While other hominids have experiences that correspond to our laughing and smiling, which occur in surprising but nonthreatening situations (e.g., during rough-and-tumble play, when tickled especially under the armpits)

(Darwin 1872), the ability to detect and enjoy humor as “mental play with words and objects” that requires resolving some kind of incongruity is unique to humans (Vrticka et al. 2013a). Detecting and resolving incongruities in humorous events is part of the cognitive component in the tripartite model of humor processing.

Several influential theories have been put forth to explain the ubiquitous role of humor in society. For instance, the superiority theory of humor postulates that humor serves to express negative feelings in a positive way, which allows for the maintenance of social order and reinforces social bonding (Wilkins and Eisenbraun 2009). On this view, aggression – or, as Plato suggested, some kind of malice toward those who are the object of the joke – is a key component of humor. Another theory proposes that humor and laughter serve as a mechanism for tension relief. Yet another account, for instance Miller’s evolutionary theory of humor, is linked to sexual selection theory and proposes that the role of humor in society is to help selection of a potential partner.

In addition to these functional theories, there are cognitive theories of humor. One such theory is the incongruity detection and resolution theory (Suls 1972). It postulates that humor arises due to detection of an incongruity, which is introduced by the simultaneous presence of incompatible elements, involving some unanticipated violation of expectations or social norms. Once the incongruity is detected, it has to be resolved by recognizing the logical mechanism on which the joke is based (e.g., ambiguity, exaggeration). The incongruity resolution allows for a reinterpretation of the information and it is typically associated with the feeling of mirth and laughter. Recent modifications of the two-stage model developed in the 1970s emphasize the emotional response following the incongruity resolution, i.e., the affective component as part of a separate stage in humor processing – the elaboration stage, following the detection and resolution of incongruity (Chang et al. 2018). This view is compatible with the findings indicating that humor and laughter can be differentially disturbed in neuropsychiatric diseases (Granadillo and Mendez 2016).

Abnormal Humor Processing

Disturbances in detecting and appreciating something as funny have been observed in a wide range of neurological and psychiatric disorders. Since humor implies certain cognitive complexity, it requires cognitive skills that are deficient in some disorders. For instance, patients with post-stroke aphasia who have a deficit in language may not be able to understand or produce verbal humor. Another type of a higher cognitive function whose deficiency may preclude humor comprehension is theory of mind, which allows us to understand other people’s minds. Since this ability is impaired in autism and schizophrenia, processing the type of humor that requires theory of mind is poor in patients with these conditions, although other types of humor may be unaffected (e.g., visual puns). For instance, reduced activation in the prefrontal cortex related to the processing of theory of mind-related humor was found in high-risk relatives of individuals with schizophrenia, and reduced ability to comprehend verbal humor together with increased response times and hypoactivation in frontotemporal and limbic cortices was found in chronic schizophrenia compared to healthy controls (Adamzyk et al. 2017). In addition, deficits in humor processing in autism may be related to these individuals’ generally poor processing of social information or poor integration of cognitive and affective information (Vrticka et al. 2013a).

Social cognition and humor processing are also affected in the diseases on the frontotemporal lobar degeneration (FTLD) spectrum, such as semantic dementia and behavioral variant of frontotemporal dementia (bvFTD). Patients suffering from these diseases show impaired accuracy in humor detection as well as proclivity for compulsive punning. While patients with bvFTD show for example preference for simple humor, patients with semantic dementia show a more general impairment of humor processing, i.e., humorlessness (Clark et al. 2015). Similarly, patients with Parkinson’s disease show a blunted response to humor, which is consistent with their overall blunted emotional responses caused by the progressive loss of dopamine-producing

neurons (Mensen et al. 2014). It has been noted that standard neuropsychological instruments are not sensitive enough to capture the alterations in humor processing associated with early stages of neurodegeneration, even though such changes may be an important early feature of the incipient disease (Clark et al. 2015).

Pathological Humor

Apart from deficits in humor perception, there are deficits related to humor production. One striking condition is pathological humor, also known as Witzelsucht (German *Witz* “joke” and *Sucht* “addiction”), which consists in disinhibited, excessive, often inappropriate joking (Granadillo and Mendez 2016). The compulsive need for joking is combined with decreased appreciation of complex, unfamiliar, or humor generated by others, except for simple humor. Witzelsucht is found in patients with brain tumors, bvFTD, strokes, infections and other lesions involving the frontal lobe, in particular the right orbitofrontal region, as well as in developmental and genetic disorders (Angelman syndrome or the “happy puppet” syndrome, Dawn’s syndrome, Williams syndrome, autism) (Granadillo and Mendez 2016; Clark et al. 2015; Rodden 2018). Currently there are no effective pharmacological or other treatments for pathological humor, although the treatment of disinhibition in psychiatric and neurological disorders or low-dose atypical antipsychotics may apply (Granadillo and Mendez 2016).

Witzelsucht, as a compulsive need to make jokes, differs from pathological laughter.

Personality and Sex/Gender Differences in Humor Processing

Humor appreciation appears to be affected by personality traits (e.g., extroversion is associated with enhanced humor processing), which is evident even during development. For instance, emotionality, shyness, and sociability moderate

humor appreciation in typically developing children who are between 6 and 13 years of age (Vrticka et al. 2013b).

In addition to the effect of individual differences in personality on humor processing, some evidence suggests that there exist sex differences in humor processing, with females showing stronger emotional reactions than males, regardless of age (Vrticka et al. 2013b). Females recruit more mental resources than males during the integration of cognitive and affective components in humor processing, and males rely more on automated processes when transiting from the incongruity detection to the emotional response (Chang et al. 2018). Furthermore, it has been observed that women prefer nonsensical and absurd humor, while men prefer humor with sexual and aggressive content. However, when humor was studied in psychological traits of gender identity such as feminine, masculine, androgynous, or undifferentiated instead of biologically defined sex classes (females vs. males), it was found that only feminine females preferred absurd humor to sexual humor, whereas masculine and androgynous females preferred sexual humor (Brodzinsky et al. 1981).

Since personality and sex/gender differences in humor processing may have implications for programs employing beneficial effects of humor in therapy, it is important to extend research on humor processing in neuropsychiatric disorders by considering how it is modulated by these factors.

The Neural Basis of Humor

Given the complexity of humor, it is not surprising that many brain areas support its processing. Attempts to determine which areas are involved in the distinct stages of humor processing suggest that incongruity detection is supported by the right middle temporal and middle frontal gyri, incongruity resolution by the left superior frontal gyrus and left inferior parietal lobe, while the elaboration stage engages the left ventromedial prefrontal cortex, the bilateral parahippocampal gyri and amygdalae (Chan et al. 2012; Campbell et al.

2015). Other evidence indicates the critical role of the left temporoparietal junction in humor detection and incongruity resolution (Slaby et al. 2015) or more generally the involvement of the “language areas”, i.e., the left inferior frontal gyrus, portions of the inferior temporal gyrus and middle temporal gyri in the cognitive aspects of verbal humor processing, and the role of the reward processing system in the affective aspect (Shibata et al. 2014). The integration of cognitive and affective components in humor processing is supported by a network of brain areas including the right middle temporal gyrus, left inferior parietal lobe and left inferior frontal gyrus, and the mesolimbic reward network (Granadillo and Mendez 2016), while the association between facial movements in laughter and the feeling of mirth during humor processing is supported by medial temporal structures (Yamamoto et al. 2015).

Damage to the right frontal lobe leads to deficits in humor processing, affecting the ability to appreciate complex humor (e.g., verbal semantic jokes) and humor generated by others, but sparing simple humor (e.g., violation of plausibility, puns, slapstick, physical humor) and self-generated humor. Deriving from the interpretations of theory of mind, this dissociation has been interpreted as “a dissociation between self vs. other referential network for humor” (Granadillo and Mendez 2016, p. 166).

The literature on the neural basis of humor processing contains some disparate findings, which may be related to methodological issues. Traditionally, lesion studies have been the standard method for establishing which brain areas are necessary for humor processing. Since relatively recently, findings on the neural basis of humor mostly come from functional neuroimaging, sometimes from transcranial magnetic stimulation studies, and to a much smaller extent from the studies using direct electrical cortical stimulation, an invasive technique which is considered the gold standard for brain-function mapping in neurosurgery. To illustrate the point, studying the neural bases of humor using neuroimaging methods such as functional Magnetic Resonance

Imaging (fMRI) is methodologically challenging, because the standard requirement that the person must not move during scanning holds despite the fact that humor is supposed to induce laughter, which would introduce additional movement artifacts in data. On the other hand, suppressing laughter may introduce other confounds and it affects brain activation patterns, even though it does not affect participants’ judgments on funniness (Korb et al. 2012). Furthermore, fMRI studies typically involve small study groups, which may preclude finding true effects and lead to false positives, which in turn leads to the problem of poor reproducibility of neuroimaging findings.

Real-Time Dynamics of Humor Processing

Consistent with the three-stage model of humor processing, event-related potential (ERP) evidence on the temporal dynamics of the contributing processes suggests that in the initial stage, i.e., during the incongruity detection, there is an enhanced negativity component at around 400 ms for funny stimuli compared to unfunny and unrelated stimuli, presumably reflecting surprise or attempts to semantically integrate the incoming information. A sustained positive component at around 500 ms has been discerned at multiple areas as an index of the incongruity resolution stage, and a late positive potential appearing after 700 ms over a range of areas (the ventromedial prefrontal cortex, bilateral amygdalae, and bilateral parahippocampal gyri) has been associated with the affective response to humorous materials (Chang et al. 2018).

Laughter

Laughter is a primal sign of social interaction, which is present in non-human primates, regardless of the presence of chuckling/laughing noise or facial movements like those occurring during human laughing (Darwin 1872). For instance, the nineteenth-century French neurologist G.B.

Duchenne observed that a pleasant surprise, such as getting delicacy during meal times, elicited in a monkey an expression in which the corners of the mouth were slightly rising, indicating satisfaction (Darwin 1872). The term Duchenne smile refers to a type of smiling that is presumably associated with spontaneously occurring enjoyment, i.e., it is a genuine smile/laughter. Unlike voluntary, fake, or deceitful smiling, involuntary smiles of enjoyment are recognizable by the contraction of the zygomatic and orbicularis oculi muscles so that the corners of the person's mouth are raising and the sides of the eyes remind of crow feet (Ekman et al. 1990). This type of smiling is elicited by "proto-humor," including rough-and-tumble play, tickling, physical mishaps, and pleasant surprise, as well as by incongruity-based conceptual humor (Vrticka et al. 2013a).

Different types of laughter are characterized by different vocal signals as well as by different cerebral activation patterns (Kreifelts et al. 2014). Laughter typically indicates safety and play behavior (e.g., tickling laughter), or cooperation, bonding, and affection. A recent study that investigated processing of slapstick (i.e., a type of physical comedy that involves misfortunate situations, like falling down) in cognitively healthy adults found that the feeling of amusement and laughter were generated only when the victim of a misfortunate situation showed bewilderment or disoriented expression, but not if the victim's facial expression showed pain or anger (Manfredi et al. 2014). Furthermore, laughter may convey social status and affect perception of social status in naïve observers. For instance, dominant, disinhibited laughter conveys a higher social status, whereas submissive, inhibited laughter conveys a lower social status; deviations from this norm, as in overt display of high status by a low-status individual, are often punished in society (Oveis et al. 2016).

Laughter is not always related to positive emotions (e.g., taunting laughter with a negative valence). It may communicate negative emotions, such as contempt and strikingly enhance emotions in negative social interactions (e.g., bullying, exclusion). For instance, the presence of a laughing

crowd considerably affects perception of verbal insults, leading to stronger and longer emotional processing (Otten et al. 2017).

In social anxiety, which is one of the most prevalent psychiatric conditions, fears related to humiliation, criticism, and rejection are exaggerated, and so is the fear of being the target of laughter. In a type of social phobia known as gelotophobia the fear of being the target of laughter is pathological (Chan 2016). While gelotophobic individuals fear aggressive humor, katagelastic individuals, in contrast, enjoy such humor, showing high levels of hostility in general and enjoying laughing at others. Not surprisingly, gelotophobic individuals, like patients with major depressive disorder and autism, have a deficit in the reward system. A recent fMRI study reported that relative to non-gelotophobic individuals, gelotophobic individuals showed less activation in the ventral mesocorticolimbic system in response to hostile and non-hostile jokes, suggesting a deficit in the reward system, and more activation in the dorsal corticostriatal system (the dorsolateral prefrontal cortex and dorsal striatum) in response to hostile jokes, which may suggest more voluntary cognitive control of emotions (Chan 2016). Other findings indicate that the left dorsolateral prefrontal cortex is the critical link between social anxiety and the negative attention bias, and that the impact of social anxiety on laughter perception is mediated by the left dorsolateral and dorsomedial prefrontal cortex (Kreifelts et al. 2014).

Sometimes lesions due to strokes, tumors, vascular malformations, or parasitic diseases result in a partial or total paresis of facial muscles, which in turn may affect the patient's ability to smile. Depending on the location of lesion, a weakening or paralysis may affect either one side or both sides of the face. Some patients with lesions in the amygdala and hippocampus experience emotional facial paralysis or contralesional mimetic palsy, a condition in which unilateral lower facial motor weakness occurs only during spontaneous smiling (and weeping), but not during voluntary smiling, which may indicate that these brain

structures link laughter and the feeling of mirth (Yamao et al. 2015).

Pathological Laughing

Disturbances involving involuntary smiling and laughing are present in a range of neurological and psychiatric conditions. Pathological laughter refers to excessive and meaningless laughing, occurring without an external/internal humor-related trigger or due to trivial or minimal stimuli, which may or may not be associated with positive feelings such as joy (Granadillo and Mendez 2016; Rodden 2018). In fact, episodes of uncontrollable laughing may occur even when the laughter is in conflict with the patient's actual mood and emotional state (Chatta et al. 2015). Furthermore, while normal laughter is at least to some extent controllable, i.e., it can be squelched even without affecting the subjective experience of funniness (Korb et al. 2012), this is not the case with pathological laughter, which is characteristically uncontrollable. For this reason, pathological laughter is sometimes classified as an involuntary emotional expression disorder, together with pathological crying and emotional lability, or as a disorder of laughing and crying, or more traditionally as pseudobulbar affect or emotional incontinence (Lauterbach et al. 2013). Pseudobulbar affect is common in neurodegenerative diseases (Lauterbach et al. 2013), including the advanced stages of Parkinson's disease where inappropriate crying occurs more often than acute mirthful or non-mirthful laughter (Chatta et al. 2015). Pathological laughter is also characteristic for post-stroke patients (Morland et al. 2015).

The most common form of pathological laughter is gelastic (Greek *gelos* "laughter") epilepsy, i.e., epileptic seizures in which laughter is a prominent symptom. The laughter during seizures often appears as unnatural and it is not necessarily associated with the feeling of mirth (Granadillo and Mendez 2016). Pathological laughter of non-epileptic nature (*fou rire* or "crazy laughter") was first described by Féré in 1903 as a prodromal sign of an impending stroke (Morland et al. 2015). It

is often related to a stroke in vertebrobasilar territory, with the most severe symptoms appearing in patients with bilateral pontine lesions. Inappropriate uncontrollable laughter may appear as the first symptom of cerebral ischemia affecting the ventral pons, left internal capsule-thalamus, left basal ganglia, or left parahippocampal gyrus. Pathological laughter is found in other conditions, such as frontal glioblastoma, primary progressive aphasia, cerebellitis, obsessive-compulsive disorder among others; it may be substance-induced and it occurs after brain trauma as well. Uncontrollable laughter is treated psychopharmacologically, with or without cognitive therapy (Morland et al. 2015).

Not only that some neurological conditions involve uncontrollable laughter, but sometimes normal laughter can trigger certain abnormal states, such as seizures, cardiac disturbances, syncope, i.e., brief periods of unconsciousness (Rodden 2018), and in particular cataplexy, i.e., a transient loss of muscle tone triggered by strong positive emotions with no change to conscious awareness (Meletti et al. 2015). The mechanism by which laughter induces cataplexy is currently not well understood. Although moments of muscle weakness due to laughter may occur even in healthy individuals, laughter-induced cataplexy is a striking and peculiar symptom, which has been associated with narcolepsy type 1 (Meletti et al. 2015). Laughter- or emotion-induced cataplexy appears to involve the amygdala, the anterior insular cortex, and the nucleus accumbens, i.e., a network of brain areas that supports reward and emotion processing.

Therapeutic Benefits of Humor and Laughter

Since humor processing engages the mesolimbic reward system, the question whether humor and laughter may have beneficial effects on therapy has merit. A positive effect of humor on resilience and coping, and its health-boosting effect have long been recognized (Wilkins and Eisenbraun 2009). Some evidence indicates that laughter has preventive and therapeutic values regardless of whether it is genuine and associated with the feeling of mirth, or voluntarily induced as in

laughter yoga. Evidence supporting the notion that humor and laughter may benefit therapy, presumably by decreasing stress hormones such as cortisol and epinephrine and enhancing activity of the mesolimbic dopaminergic reward system, comes from studies in a range of medical fields. However, the mechanism underlying this beneficial effect remains unclear. Thus, the effects of humor and laughter on mental and physical health and well-being require further studying.

Conclusion

Humor is a complex experience, involving detection and resolution of incongruity that is typically associated with laughter and the feeling of mirth. Different neurological conditions are associated with different humor-related abnormalities, ranging from the ability to comprehend only simple or self-generated humor to impairments affecting specific types of humor (verbal, theory of mind-related) to inability to appreciate any kind of humor. In terms of humor production, a striking condition is pathological humor, i.e., a compulsive need to make jokes. A related set of deficits pertains to pathological laughter, i.e., excessive and meaningless laughing that is found in a range of neurological and psychiatric disorders.

Definition

The outermost layer of the brain, the *cerebral cortex*, consists of billions of brain cells or *neurons* that compose perplexing neuronal networks that are associated with humans' higher-order cognitive functioning.

Introduction

Ever since the appearance of mammals around two hundred million years ago, the cerebral cortex has gained an insurmountable reputation as the most significant brain region (Robert 2002). The *cerebral cortex*, or the outer layer of neural tissue of the brain, has grown for as long as natural selection favored its expansion. The cerebral cortex plays a leading role in many higher-order cognitive processes such as memory, attention, thought, language, perception, awareness, and consciousness, which are all hypothesized to have been evolutionarily advantageous among humans.

The Mammalian Brain

Mammals are generally born with the most amounts of brain cells or *neurons* their brain will ever have. As the brain matures, connections are made between neurons and form compact and

complex neuronal networks. In an attempt to save space, the brain folds in on itself to better shelter its expanding neuronal networks, which distinguishes the mammalian brain from others (Hofman 2014; Robert 2002). Among current living species, mammals possess the largest brain-to-body size ratio. The physical sensations mammals can experience by visual, auditory, olfactory, and physical stimuli are a result of the brain's general sensory system that is distributed throughout the cerebral cortex (Robert 2002; Rowe et al. 2011). Among the mammals, primates have the most amounts of neurons in their brain's cerebral cortex (Herculano-Houzel 2009).

Evolution of the Cerebral Cortex

Discovering new means to obtain food and to adapt to ever-changing environments may have been the catalyst of the evolution of the cerebral cortex (Hofman 2014). Eating cooked food is an exclusive feature of modern humans or *Homo sapiens*. Evolutionary anthropologists and psychologists, today, are beginning to accept that superfluous nutrition and sanitation from cooked food paved way the primate brain to become the most advanced nervous system (Carmody and Wrangham 2009).

The homo sapien brain contains about eighty-six billion neurons; sixteen of which are housed in its cerebral cortex (Herculano-Houzel 2009), which makes the homo sapien cerebral cortex larger of any other great ape (Dyer 2016). Although larger size of the brain and cerebral cortex are associated with higher intelligence, size is no longer considered a proxy for number of neurons (Herculano-Houzel 2009). Fossils from the Neandertals, an ancestral relative of *Homo sapiens*, had an even larger brain size than modern humans' (Harari 2015). The complexity of the established neuronal networks within the cerebral cortex, however, is believed to be related to *Homo sapiens*' intellectual gifts (Herculano-Houzel 2009; Hofman 2014).

The cerebral cortex can be divided into four regions called *lobes*. The frontal lobe (1) specializes in higher-order cognitive processes like

abstract thinking and reasoning, problem solving, language, and even the experience of several affective states. The parietal lobe (2) houses neuronal networks for movement and orientation, as well as the recognition and perception of external subjects. The occipital lobe (3) primarily specializes in visual processing, whereas the temporal lobe (4) specializes in the processes of recognition and perception of auditory stimuli, memory, and speech with an emphasis on auditory processing (Kinser 2000).

Psychological Adaptations of the Cerebral Cortex

An increased cerebral cortex expedited the emergence of novel behaviors. While the environmental pressures on *Homo sapiens* diversified, the cerebral cortex evolved to become the most versatile biological system within the species. The creation of tools and weapons, the discovery and manipulation of fire, the ability to discern edible from inedible food, the knowledge of which types of plants would remedy an ailment, and other survival skills are all products of cerebral cortex activity (Hofman 2014). The ability to speak a language further intensified humans' social nature (Harari 2015; Robert 2002), which then contributed to the upbringing of emotional and social intelligences (Hofman 2014).

Humans' capability to learn from experiences, like other organisms', is subject to the laws of biological evolution. Modern behavioral phenomena, such as government, school, marriage, social prejudice, and war, are being linked to the nature of human psychology. Evolutionary psychology seeks to enlighten the behavioral science community about the traces of neurological evolution within universal behavior. Evolutionary psychologists acknowledge that not every observed behavioral pattern today originated as a particular function. The intrinsic pleasure while listening to music, for example, is unlikely to have been an evolved adaptation to a particular problem. Romantic love may be constituted by multiple and independent psychological mechanisms, but by-products and random effects are still subject to

both biological and psychological evolution (Fisher et al. 2006).

Conclusion

The mammalian brain has been in position to surpass any nervous system for millennia. Its talent to fold to conserve space for its neuronal networks deems itself as the most elusive organ to understand. Even while the brain drains a significant portion of the body's energy, early humans' discovery of fire and cooked food provided a plethora of its nutrition. The homo sapien brain may not be the largest hominid brain ever recorded, but its countless neuronal connections, particularly within the cerebral cortex, spoil the species with higher intelligence and the ability to experience affect. Precise environmental pressures that precipitated neuronal proliferation remain uncertain, but novel environmental conditions, such as society and culture, pose as new selection pressures that will continue to drive the evolution of the cerebral cortex and the evolution of human psychology.

Newborn Behavior

Niki Christodoulou and Xenia Anastassiou-Hadjicharalambous
University of Nicosia, Nicosia, Cyprus

Synonyms

Primary circular reactions, Sensorimotor stage

Definition

During the first year of life, children engage into exploratory behaviors in order to become familiar to and learn about the surrounding world.

Introduction

During their first year of life, children engage mainly, in what Jean Piaget called sensorimotor play or practice play (Piaget 1962). This consists mainly of already experienced, sensory and motor activities, which are repeated for the absolute pleasure of doing so (Hughes 2010) and thus considered as “playful” behavior. Piaget (1962) suggested that this form of play is integral for the child’s intellectual development and that the young child moves through a number of different substages of sensorimotor progression. In this section, we will explain the different stages of cognitive development as well as how the newborn child moves through the period of sensorimotor play to acquire the skills and abilities to think on their own.

Stages of Cognitive Development

Piaget suggested that people progress through four cognitive developmental stages: the *sensorimotor* stage, the *preoperational* stage, the *concrete operational* stage, and the *formal operational* stage. In each stage, children demonstrate new abilities, which allow them to

experience and understand the world in qualitatively different ways than they had before (Siegler et al. 2011).

1. In the sensorimotor stage – from birth to 2 years of age – infants experience basic sensory and motor abilities through which adult intelligence develops. Through these abilities young children explore the world and gain information about the objects and people in it (Siegler et al. 2011). In this stage, young children live mainly in the here and now while their intelligence levels are based on their immediate actions and perceptions (Siegler et al. 2011).
2. In the preoperational stage – from 2 to 7 years of age – preschoolers can remember their experiences for longer periods of time and develop more sophisticated ideas as they can now represent their experiences in language and mental imagery (Siegler et al. 2011). Yet, according to Piaget, they still lack the ability to form *mental operations*, that is, forms of reasoning as part of an organized system of mental activities. For example, during the preoperational stage, a young child would be unable to form the idea that pouring a liquid from one glass into a different shaped glass does not change the amount of liquid (Siegler et al. 2011).
3. In the concrete operational stage – from 7 to 12 years of age – children can reason logically about concrete objects and events (Siegler et al. 2011). For example, they can now understand that the amount of liquid is unchanged when it is poured from one glass to a differently shaped one. Yet, they still cannot think in abstract terms, neither to test out their beliefs through scientific experiments.
4. In the last stage of cognitive development, known as the formal operational stage – age 12 and beyond – children can think sophisticatedly about abstract ideas as well as hypothetical scenarios (Siegler et al. 2011). They can also test out their beliefs and gain appropriate conclusions by forming scientific experiments.

With this overview of Piaget’s cognitive development theory, we can examine in greater extent the

changes that occur during the sensorimotor period. Specifically, we consider how newborn children behave during this stage in terms of sensorimotor play and exploration.

Sensorimotor Play

Sensorimotor play is acquired gradually during the first 18 months of life before the newborn child moves to symbolic or make-believe play (Hughes 2010). In fact, Piaget gave a detailed description of the process by which children develop their own capacity for thinking by carefully observing how his own children were behaving (Smith et al. 2015). Based on these observations, he divided the sensorimotor play period into three behaviors, which he called circular reactions (Hughes 2010).

Primary Circular Reactions

This is the earliest form of sensorimotor play – the *primary circular reaction*. During this period, which begins from birth and usually lasts up to 4 months of age, an infant accidentally discovers a pleasing sensory or motor reflex activity that is related to its own body (Hughes 2010). The infant experiences enjoyment and thus repeats the activity (Hughes 2010). Piaget used the term “circular” to emphasize the way that children repeat newly reflex experiences, notably the ones that are pleasing such as scratching or grasping (Smith et al. 2015). The term “primary” relates to basic behaviors that the child learns to exhibit, from the reflexes of the initial period (Smith et al. 2015). Based on his own 8-week-old son’s behavior, Piaget illustrated the concept of primary circular reaction by explaining: “Laurent scratches and tries to grasp, let’s go, scratches and grasps again, etc. . . . At first, this can only be observed during feeding. Laurent gently scratches his mother bare shoulder. [The next day] . . . Laurent scratches the sheet which is folded over the blankets, then grasps and hold it for a moment, then lets it go, scratches it again, and recommences without interruption” (Piaget 1963, p. 191).

In behaving as he did, Laurent’s actions could be perceived, as play with objects rather than play

centered on his own body (Hughes 2010). Yet, according to Piaget this is not the case as he explains that the play is the physical action such as the grasping or scratching (Hughes 2010). According to this idea, an infant is interested in the action itself, rather than being interested in the object they are performing the action on (Hughes 2010). For example, the same action is performed on any object that happens to be around the infant. In this matter, we can appreciate that children, even early on in their life, can manipulate objects once they are given to them. Indeed, such reflex behaviors are purposeless and lack intellectual awareness – two essential elements that characterize object play (Hughes 2010).

Secondary Circular Reactions

From the age of 4 until the age of 10 months, children move to the next stage of circular reactions that is distinctly different (Piaget 1962). They are now interested on objects and the consequences of their actions, instead of being focused on their own body and repeating actions based on early reflexes (Smith et al. 2015). They engage in what Piaget called *secondary circular reactions*, the intentional alteration in their surroundings by making interesting things happen such as moving a hanging object by hitting it (Smith et al. 2015). Particularly, secondary circular reactions refer to the young infant’s enthusiasm to repeat newly initiated actions, aiming to influence their surrounding environment.

To illustrate the difference between primary and secondary circular reactions, Piaget described the behavior of his daughter Jacqueline, at 5 months of age. He describes: “Jacqueline looks at a doll attached to a string, which is stretched from the hood to the handle of the cradle. The doll is at approximately the same level as the child’s feet. Jacqueline moves her feet and finally strikes the doll, whose movement she immediately notices. . . The activity of the feet grows increasingly regular whereas Jacqueline’s eyes are fixed on the doll. Moreover, when I remove the doll Jacqueline occupies herself quite differently; when I replace it, after a moment, she immediately starts to move her leg again” (Piaget 1936/1952, p. 182). Thus, we can see that Jacqueline’s interest

has moved from her own body toward her surrounding environment and the consequences of her actions. In behaving as she did, the young girl seemed to have detected a relation between her movement and the doll's, and was involved in secondary circular reaction.

During secondary circular reaction substage, as children continue to grow, they also start to combine different behavioral schemas; what Piaget called *coordination of secondary circular reactions* (Smith et al. 2015). In the following example, we can see how Jacqueline combined different schemas such as “sucking” or “grasping” an object in a series of coordinated actions when a new toy is introduced to her at 8 months of age: “Jacqueline grasps an unfamiliar cigarette case which I present to her. At first, she examines it very attentively, turns it over, then holds it in both hands while making the sound ‘apff’ (a kind of hiss which she usually makes in the presence of people). After that she rubs it against the wicker of her cradle then draws herself up while looking at it, then swings it above her and finally puts into her mouth” (Piaget 1936/1952, p. 284). Jacqueline's behavior illustrates how children begin to combine several schemas to achieve goals or get through new situations.

Tertiary Circular Reactions

While the newborn child between 8 and 12 months of age would engage in a repetition of their actions in order to enjoy an interesting outcome, the young 1-year-old progresses to the next level. Although children would still repeat the previous stage, they are not repeating it precisely but instead, they try to vary the activity, a new behavior known as a *tertiary circular reaction* (Hughes 2010). Children's behaviors are now more flexible and this could lead to new results (Smith et al. 2015). By repeating actions in alternative ways young children are, essentially, applying already established schema to new situations and needs (Smith et al. 2015).

Consider the example of Piaget's daughter Jacqueline – now 13-month-old – in her bath: “Jacqueline engages in many experiments with celluloid toys floating on the water... Not only does she drop her toys from a height to see the

water splash or displace them with her hand in order to make them swim, but, she pushes them halfway down in order to see them rise to the surface. Between the ages of a year and a year and a half, she amuses herself by filling her sponge with water and pressing it against her chest, by running water from the faucet... along her arm, etc.” (Piaget 1936, p. 273). The playful element in this form of circular reaction is evident, as the child seems to enjoy their time with novel objects as well as actively trying to create new interesting experiences.

As the young child progresses through the previous stages of sensorimotor play, they learn to act directly on their surrounding environment via their sensory and motor schemas. According to Piaget, the sensorimotor play period ends when children finally achieve what we call *internal representation* (Smith et al. 2015). Internal representation refers to the child's ability to act indirectly on the world because they have now a mental representation of the world, and this ability is not acquired until the newborn child reaches the age of 18–24 months (Smith et al. 2015). This means that, children are able to manipulate their mental representation of the world such as being able to think and plan.

Conclusion

According to the Piagetian theory of cognitive development, infants progress through four developmental stages where they gradually acquire the skills necessary to experience and understand the world around them. As Piaget further suggested, young children develop their own capacity for thinking through the period of sensorimotor play. During this period, the young child progresses from very simple and basic reflex actions at birth to more complex behaviors at the end of each stage. At first, infants' motor or sensory activities are related to their own bodies with concrete goals being the ultimate outcome, such as shaking a rattle and listening to the sound it makes. Later, infants' activities are mainly focused on the surrounding world with more abstract goals such as differing the heights from which objects are dropped and watching what happens as well as

how the different effects vary. Young children also acquire the ability to form mental representations such as remembering another person's behavior and imitating it the day after it occurred. It is only toward the end of the period that children develop this ability to mentally represent the world as well as to manipulate their thoughts and construct their own knowledge in response to their experiences.

Definition

A book, written by Judith Rich Harris, which focuses on the theories and research that explain the individual differences in personality.

Introduction

No Two Alike: Human Nature and Human Individuality is a book written by independent psychological scientist Judith Rich Harris and was published by W. W. Norton in 2006. The book – written in the theme of a detective story – investigates the potential causes of individual differences in personality as though they are suspects in a crime. Throughout this investigation, Harris cites research in many areas of psychology and biology – including traditional developmental psychology, twin studies, animal research, and behavioral genetics, among others. Harris' investigation eventually leads her to present her own theory regarding the causes of individual differences in personality.

About the Book

No Two Alike begins by addressing many of the traditional and popular theories regarding why individuals differences in personality exist. These five theories – considered “red herrings” as they mislead researchers away from the true causes of individual differences – include the environment, heritability, gene-environment interactions, indirect genetic effects (also known as gene-environment correlations), and birth order. Although Harris does not fully discount these potential causes of individual differences, she cites important findings made in the areas of behavioral genetics and social psychology as evidence that these cannot fully account for all of the causes of individual differences across humans.

After eliminating those “red herrings,” Harris posits her own theoretical model that explains how and why individual differences in personality exist. This model contains three evolved psychological systems – each of which is distinct from the other. The first system – referred to as the *relationship system* – accounts for short-term behavioral differences based on interactions with the people in one’s environment. The relationship system allows individuals to store information regarding the people around them (e.g., who is kind, who is aggressive, who is trustworthy, etc.) allowing each individual to know how to act and respond when in the presence of each specific individual. This relationship system allows for variance in behavior but only accounts for short-term changes in behavior – as these behaviors only change when in the presence of different people.

The second system – known as the *socialization system* – is a product of socialization from many sources – parents, peers, etc. This system allows for individuals to develop an understanding of the social norms and accepted behaviors in their environments. This system – which supports Harris’ hypothesis from her previous book, *The Nurture Assumption* – illustrates how parents are not the only source of socialization for their children. Although children are socialized by their parents, they are also socialized by their peers – and peers continue to have a greater effect than

parents’ as the children grow up. These various sources of socialization lead to differences in social behaviors based on what is deemed appropriate within each group. For example, an adolescent knows that s/he may engage in certain behaviors – such as swearing – in the presence of his/her friends, but that adolescent also knows that s/he should not – and therefore usually does not – swear when in the presence of his/her parents.

The third and final system – the *status system* – encourages competition with one’s peers. This system accounts for behavioral differences between individuals and their peers by examining peers as rivals for status and/or resources. The status system then collects knowledge of oneself and interacts with the socialization system to help elevate one’s social status over his/her peers. Harris argues that this system not only accounts for individual differences in long-term personality development, but it also accounts for individual personality differences between identical twins (i.e., identical twins may act differently from each other because they are engaging in different behaviors to achieve higher status than the other).

Conclusion

No Two Alike has been met with positive reviews by journalists and evolutionary psychologists (Kaighobadi and Shackelford 2008; Saletan 2006). It was written in a compelling detective-style format that is often viewed as fun and attention-grabbing. In this book, Harris provides evidence for rejecting some of the more traditional and popular theories regarding the causes of individual differences while also providing a new theory – rooted in evolutionary psychology – that adequately explains individual differences in personality.

Noam Chomsky

Samuel Sayantan Mandal
Concordia University, Montreal, Quebec, Canada

Introduction

Professor Noam Chomsky, born December 7, 1928, as Avram Noam Chomsky to middle-class Jewish working parents in East Oak Lane, Philadelphia, is an American linguist, cognitive scientist, logician, philosopher, and political activist. Often referred to as “the father of modern Linguistics,” “the world’s most important intellectual,” etc., Chomsky has made pioneering contributions to multiple fields, including Linguistics (a field he is primarily credited with founding in its modern form), Logic, Abstract Algebra, Artificial Intelligence and Machine Learning, Formal Languages, Cognitive Science, Cognitive Psychology, Philosophies of Mind and Language, and Anarchist and Syndicalist political theories, and is considered to be one of the pillars of Analytic Philosophy, particularly in the Rationalist tradition. Ranked as “among the eight most cited scholars, ever,” Chomsky is currently Professor Emeritus of Linguistics at the Massachusetts Institute of Technology, where he has held

office for over half a century, and Laureate Professor of Linguistics at The University of Arizona.

Early Life

Avram Noam Chomsky was born on December 7, 1928, in the East Oak Lane neighborhood of Philadelphia, Pennsylvania (Lyons 1978). His father was William “Zev” Chomsky, an Ashkenazi Jew originally from Ukraine who had fled to the United States in 1913. Having studied at Johns Hopkins University, William went on to become school principal of the Congregation Mikveh Israel religious school and in 1924 was appointed to the faculty at Gratz College in Philadelphia. Chomsky’s mother was the Belarusian-born Elsie Simonofsky (1904–1972), a teacher and activist whom William had met while working at Mikveh Israel (Lyons 1978).

Chomsky’s primary education was at Oak Lane Country Day School, an independent Deweyite institution that focused on allowing its pupils to pursue their own interests in a non-competitive atmosphere. It was here, at the age of 10, that he wrote his first article, on the spread of fascism, following the fall of Barcelona to Francisco Franco’s fascist army in the Spanish Civil War. At the age of 12, Chomsky moved on to secondary education at Central High School, where he joined various clubs and societies and excelled academically but was troubled by the hierarchical and regimented method of teaching used there. During the same time period, Chomsky attended the Hebrew High School at Gratz College. From the age of 12 or 13, he identified more fully with anarchist politics (Lyons 1978).

Education

In 1945, Chomsky, aged 16, embarked on a general program of study at the University of Pennsylvania, where he explored philosophy, logic, and languages and developed a primary interest in learning Arabic. Living at home, he funded his undergraduate degree by teaching Hebrew. However, he was frustrated with his experiences at the university and considered dropping out and

moving to a kibbutz in Mandatory Palestine. His intellectual curiosity was reawakened through conversations with the Russian-born linguist Zellig Harris, whom he first met in a political circle in 1947. Harris introduced Chomsky to the field of theoretical linguistics and convinced him to major in the subject. Chomsky's B.A. honors thesis was titled "Morphophonemics of Modern Hebrew" and involved his applying Harris's methods to the language (Boeckx and Piattelli-Palmarini 2005). Chomsky revised this thesis for his M.A., which he received at Penn in 1951; it would subsequently be published as a book (Boeckx and Grohmann 2013; Boeckx and Piattelli-Palmarini 2005). He also developed his interest in philosophy while at university, in particular under the tutelage of his teacher Nelson Goodman. From 1951 to 1955, Chomsky was named to the Society of Fellows at Harvard University, where he undertook research on what would become his doctoral dissertation (Barsky 1998; Lyons 1978; Otero 1994).

Basic Ideas I. Science

Plato's Problem

In Linguistics Chomsky holds a position akin to that of Isaac Newton in Physics during and after enlightenment (Dawkins 2015). Evolutionary Psychologist Steven Pinker remarked, "Whether or not Chomsky provided all the right answers, Linguistics and Cognitive Science will always be dominated by the questions Noam Chomsky has asked." In stark contrast to the behaviorist zeitgeist fashionable in the 1940s and early 1950s, Chomsky brought about a Kuhnian paradigm shift in the study of the human mind, which he claimed is the cradle of language, by directly linking it to mainstream biology and arguing that the adult mind with all its knowledge systems is a biological organ, much like the human digestive system (Chomsky 1959a). Indeed, years after Chomsky kickstarted what came to be known as the *cognitive revolution*, immunologist Niels Jerne compared the human digestive system to Chomsky's theory of Grammar ("Niels K. Jerne – Nobel Lecture," n.d.).

Perhaps the best introduction to Chomsky's thoughts and works in Linguistics is manifest in the introductory lines of *Syntactic Structures*:

Syntactical investigation of a given language has as its goal the construction of a device for producing the sentences of the language under investigation.... The ultimate outcome of [such] investigations should be a theory of linguistic structures in which the descriptive devices utilized in particular grammars are presented and studied abstractly.... One function of this theory is to provide a general method for selecting a grammar for each language, given a corpus of this language. (Chomsky 1957/2002)

For Chomsky one of the fundamental issues in rationalist epistemology concerns the problem of "creativity" (Aarsleff 1970; Bever 2009; Chomsky 2009). Namely, how is it that human beings whose contact with nature is so brief and transient come nonetheless to learn so much of it? Applying this general observation to linguistic phenomena, Chomsky asks how is it possible for a child to instinctively create new utterances to which it has never been exposed specifically, based only on exposure to a fraction of the possible sentences of a language. Indeed, Chomsky points out that the total number of possible sentences in a language is *infinite* and that this infinity (discrete infinity: infinite number of sentences, with discrete whole numbers of words in them, but never fractions of words) itself is made possible by the fact that users can create completely novel utterances at any given instance (Chomsky 2007). Thus, Chomsky observes, the child placed in its natural environment is exposed to a limited amount of experience, and yet what the child comes to possess in the form of knowledge from this limited environment far exceeds its experiences. This gap between what the child is given, and what it comes to possess, and the problems concerning how the child is able to bridge this gap, Chomsky terms *Plato's Problem*, after the classical philosopher who first observed this tendency of the Sapiens' minds (Chomsky 1959b).

This program contrasts, and falsifies, Skinnerian Behaviorism (Chomsky 1959a) which held that language is a result of associations between words. Because users can create completely novel

associations between words in the form of new sentences, such a theory is automatically rendered untenable. While Chomsky's devastating criticism of Skinner's *Verbal Behavior* (Chomsky 1959a, 1967) is often taken to be the most important cause behind the decline of radical behaviorism, the idea that prior constraints on learning space and hypotheses impose severe limits on what can be inductively learned has since spread beyond psychological nativism as evidenced in Wolpert's *No Free Lunch* (Wolpert and Macready 1997).

Principles and Parameters

Chomsky's proposed methodology to scientifically approach Plato's problem was first proposed in *Aspects of the Theory of Syntax* (Chomsky 1965), also known as *standard theory*, and later revised as the *standard extended theory* which was developed and revised throughout the 1970s during the early years of generative grammar. Within this framework it is hypothesized that the child is genetically endowed with an innate hypotheses space, a format for possible grammars of natural language, and the child in the process of growth and development constructs a number of possibilities to externalize. The selection of the ultimate externalized grammar is hypothesized to be the one that selects the least number of rules, that is, one that manifests a minimal implementation of the system to achieve discrete infinity.

However, since this approach proved too cumbersome, Chomsky and colleagues soon proposed a newer alternative in the form of the *principles and parameters approach* (PnP) (Chomsky 1993, 1995). First introduced by Chomsky in *Lectures on Government and Binding, or The Pisa Lectures* (Chomsky 1981/1993), and later elaborated further in *Knowledge of Language* (Chomsky 1986), PnP hypothesizes that the architecture of language is constructed through *Principles*, invariant and constant across languages, and *Parameters*, also universal but adjustable in individual languages, thereby yielding linguistic diversity. One set of principles, for example, restricts the possible distribution of pronominals, reflexives, and anaphors

in sentences of the world's languages to specific predetermined hierarchical spots in phrasal structures and is referred to as *the binding principles*. All languages adhere to binding principles, either explicitly or vacuously. Parameters on the other hand, such as the PRO-drop parameter, are hypothesized to have individual preferences for how they are implemented in individual languages. For instance, Japanese is a PRO-drop language in which certain categories of pronouns are overtly omitted because they are inferable otherwise from the structure. Other languages may choose to not drop the PRO. While parameters themselves are posited to be innate, that is the total number of possible parameters are finite and limited to an universal set, not all languages must instantiate all parameters, unlike principles.

Minimalist Program and the Biolinguistic Link

The system of grammars described above is often referred to as *transformational* and *generative*, or *transformational-generative* (Chomsky 1959b, 2002), because in this framework, grammar is composed of a system of *representations* in the mind, manipulated computationally by innately specified *syntactic rules*, thus deriving structures from elementary primitives (generative) and then modifying existing structures to derive newer ones (transformation). The system can thus be conceptualized in a twofold fashion with regard to how it makes possible and then implements languages in human brains. Traditionally, theories of grammar are *computational-representational* (C-R) (Embick and Poeppel 2015; Poeppel et al. 2012) theories which assume that the human mind is genetically endowed with a set of innate concepts and symbols (representations) which are used as constituents by algebraic computational rules to create bigger and more complex structures. Thus, the meaning (or semantic content) of a structures is derived not *just* from the combined semantic contents of its constituents but also from (a) how the constituents are combined in a given structure to make larger constituent structures and (b) how constituents and (c) constituent structures

in the larger structure relate and refer to each other. For instance, in the sentence

[[John told Mary]_i][that [Bill loves her_i]]

[John, Bill, Mary, love, her, that] form a set of constituents, while [John told Mary] and [Bill loves her] form larger constituent structures capable of being complete utterances on their own but indeed are combined within a larger structure to derive our example sentence. The meaning of this final superstructure, while dependent on the meanings of the constituents, is also contingent on how individual constituents, for instance, “Mary” and “her” relate to each other. Since “Mary” and “her” carry the same index “i,” we know that the “her” that “Bill” loves is in fact “Mary.” Chomsky’s main hypothesis is that such constituent structures, the indices (such as “i”), and the rules that compute and implement them are part of the innate mechanisms of our brains. Thus, “Mary,” the intended listener of our example utterance, can listen to “John” produce the same and, in spite of the fact that linear acoustic speech signals contain neither brackets nor indices, can mentally recompute the intended structure, and therefore the intended meaning, reflexively and without ever being explicitly aware of the fact that she is doing so (Chomsky 1959b, 2007; Hauser et al. 2002; Hauser and Spelke 2004).

In the 1990s, Chomsky’s research focused on what he called the “minimalist program” (Chomsky 1995), which attempted to demonstrate that the brain’s language faculties are the minimum faculties that could be expected, given certain external conditions that are imposed on us independently. In other words, Chomsky began to place less emphasis on something such as a universal grammar embedded in the human brain and more emphasis on a large number of plastic cerebral circuits. And along with this plasticity would come an infinite number of concepts. The brain would then proceed to associate sounds and concepts, and the rules of grammar that we observe would in fact be only the consequences, or side effects, of the way that language works. Analogously, we can, for example, use rules to describe the way a muscle operates, but these rules

do nothing but explain what happens in the muscle; they do not explain the mechanisms that the brain uses to generate these rules.

The specifics of the biolinguistic program (Bever 2003, 2009; Boeckx and Grohmann 2013; Boeckx and Piattelli-Palmarini 2005; Chomsky 2005b, 2007; Medeiros et al. 2016) concern approaching every aspect of language – sound, meaning, and structure – as functions of an organ of the mind. While Chomsky emphasizes that language itself is a function of the biological organ known as *the faculty of language*, a module of the human cognitive system devoted to language specifically, the precise nature and architecture of this module remains a hotly debated avenue of research. Chomsky himself has continuously revised his position on this issue, with the latest version of his theory making a distinction between *the faculty of language-Narrow* (FLN: the core architectural component of the faculty not attested anywhere else in the living world) and *the faculty of language-Broad* (FLB: the aspects of the faculty portions of which may be present in other animals) (Hauser et al. 2002, 2014; Hauser and Spelke 2004). In these versions of his work, along with his colleagues like Mark Hauser, Tecumseh Fitch, and Massimo Piattelli-Palmarini et al. (Berent 2016; Boeckx and Piattelli-Palmarini 2005; Medeiros et al. 2016; Piattelli-Palmarini 2013), Chomsky has claimed that the core component of FLN specific just to humans is a single operation called *MERGE*, which merely takes two constituents and creates an unordered set by merging them together. It is claimed that *MERGE* meets computational minimality requirements by creating simple unordered sets instead of ordered ones.

MERGE $x, y \rightarrow [x, y] (= [y, x])$

The details of how a formal operation like *MERGE* is to be implemented on a biological substrate, how such hierarchical structures get linearized, and what kind of neural structures and operations are involved in doing so constitute the core of biolinguistic research carried out interdisciplinarily by psychologists, linguists, neurobiologists, and evolutionary biologists.

Politics and Activism

Robert Barsky's biography, called *Noam Chomsky: A Life of Dissent* (Barsky 1998), and published by MIT Press in 1997, contains a useful discussion of his early years and the development of his politics. Today, Chomsky is distinguished for his innovative work in the field of linguistics, but his wider public renown is due to his authoritative voice as a critic of US foreign and domestic policy (Antony and Hornstein 2003; Otero 1994).

Turning to sociopolitical issues, we mainly observe Chomsky working on ideas of free development, not unlike those underpinning his approach to language as some have claimed. Chomsky's main idea is that humans do not need much in the way of external control in order to form wholesome and productive social relationships. He has routinely advocated for a society moving toward voluntary organizations and eliminating as much as possible the structures of hierarchy and domination (Herman and Chomsky 2002; Lyons 1978). Chomsky views rigid hierarchical control by structures of authority as antithetical to the nature of human development and argues that such outside interference has a stifling effect on intellectual development and social life in general. While Chomsky maintains that social institutions are a necessity, he rigidly opposes the hierarchical organization of such structure and the privatization of means of production that leads to concentration of wealth. Chomsky argues that concentration of wealth leads to concentration of power (Chomsky 2014).

Chomsky's critique of the state is mainly directed toward his own (Chomsky 2003b). He turns his analytical anger on Washington's cruel maltreatment of third world people, its ruthless foreign policies and disregard for international law, its abuse of US citizens and residents, and its violations of democracy and Constitutional Law (Chomsky 1999; Herman and Chomsky 2002). He argues that this pattern of behavior became dominant after World War II left the US state in a position of unchallengeable power. It was US aggression against Vietnam that has usually been identified, including by Chomsky himself (Chomsky 2003a, 2005a), as the dominating factor that lead Chomsky to become a critic of US foreign policy. His essays

on the war are collected in *American Power and the New Mandarins* (Chomsky 2003a) and in *At War With Asia* (Chomsky 2005a); these books remain relevant today. Chinese readers may have a particular interest in what he has written about the Vietnam War since the US invasion was justified in the USA and around the world by the need to contain China.

Chomsky's logic is to apply universal principles when judging the behavior of government. In particular, Chomsky argues that unlike relativist norms often employed by politicians, an unjust course of action is wrong irrespective of who it benefits. That is, "if its wrong when they do it, then its wrong when we do it." In *Hegemony or Survival: America's Quest for Global Dominance* (p. 4) he writes, "Those who are seriously interested in understanding the world will adopt the same standards whether they are evaluating their own political and intellectual elites or those of official enemies. ... Truth [is] veiled by intentional ignorance that makes a crucial contribution to ongoing crimes" (Chomsky 2004). He regards the quest for truth and the struggle against official evasion and mendacity as the "responsibility of intellectuals" (Chomsky 1967).

Definition

The impact of Noam Chomsky on the field of linguistics, particularly the evolution of language.

Introduction

Noam Chomsky (born December 7, 1928) is one of the most influential contemporary thinkers. His huge impact surpasses linguistics to include

psychology, philosophy, or computer science, among other fields. The advent of Chomsky's generative grammar in the second half of the twentieth century challenged the traditional view that considered language to be a purely cultural trait deriving from our great intelligence and unlimited learning capacities, by claiming that language is an innate trait, part of the human biological endowment.

It would be hard to provide an overall presentation of Chomsky's linguistic work, for it has been crucial in many topics: nativism, language and mind, universal grammar, the poverty of the stimulus, language acquisition, language structure, etc. All of these topics have been widely discussed and are well known. Therefore, this piece will discuss a perhaps lesser-known topic, Chomsky's views on language evolution, characterizing the evolutionary processes by which language could have come into being. This is especially relevant, for some scholars (Dennett 1995) have suggested that according to Chomsky language could not have evolved.

The structure of the piece is as follows: first, Chomsky's conception of language is summarized; then, his main ideas about language phylogeny are brought to the fore. Finally, some criticisms are raised to his approach, although without the abandonment of the core theoretical premises Chomsky adhered to.

Chomsky's View on Language

In the 1960s, Chomsky challenged the traditional conception of language by claiming that this trait is biologically rooted (i.e., an innate trait), thus belonging to the human biological endowment. Accordingly, the biolinguistic approach (Jenkins 2000) analyzes language from a biological perspective, by assuming that its study should be conceived of as a branch of human biology (Chomsky 1980). The innate principles (taken to be genetically seated) responsible for language acquisition make up the universal grammar. Language grows in the mind; given a minimum of experience, those principles are triggered, thus making it possible to attain the steady state of

linguistic knowledge that characterizes native speakers. When language development comes to an end, the individual possesses a mental grammar, or I(nternal)-language, by which infinite sentences can be generated/interpreted.

One point is in order: the notion of language is ambiguous, for it covers many different aspects (historical, social, cultural, etc.), but the biolinguistic approach is not concerned with aspects like those. To avoid terminological problems, the notion of faculty of language (henceforth, FL) will be used instead to refer to language as a biological capacity. Its architecture will be briefly presented, for it is such an architecture that is to be explained in evolutionary terms.

From the view of the Minimalist Program (the current Chomskyan model; Chomsky 1995), FL (syntax) is a natural computation system that resides in the mind/brain of all human beings (pathologies aside). In that definition, two notions are to be highlighted: *computational* means that FL is a system of information-processing based on the capacity for manipulating mental elements and performing computations on them, while *natural* means that FL is an innate mental organ restricted to our species (at least, currently).

From the point of view of the mental architecture, FL is a bridge faculty connecting the articulatory-perceptual system (henceforth, A-P), in charge of our visual, oral, gestural, and auditory activities, and the conceptual-intentional system (C-I), responsible for the production of intentional thoughts and attitudes about the world. Both capacities, though, are independent: on the one hand, not every thought needs to be externalized; on the other, sounds can be produced without associated meaning. FL provides the channel by which representations of A-P and C-I systems (sounds/gestures and meanings) become accessible to each other. FL takes elements from the lexicon and "generates an infinite array of hierarchically structured expressions" (Chomsky 2010, p. 45). This capacity is enabled by recursion, which permits to embed constituents within constituents of the same type. FL connects to the A-P and C-I systems through two interfaces: an external sensorimotor interface with the A-P system, in charge of the production and perception of the

expressions generated by FL, and an internal conceptual-intentional interface with the C-I system, which links the mental expressions with their semantic and pragmatic interpretation, concepts, reasoning, etc. Accordingly, any expression generated by FL receives an interpretation at both interfaces.

The next section approaches how the architecture of FL could have come into being evolutionarily.

Chomsky and Language Evolution: A Conceptual Guide

This section will provide the key points of Chomsky's thought on language evolution. For the sake of clarity, the section is organized into questions and answers.

Did Language Evolve from Animal Communication?

Because human and nonhuman animals communicate with conspecifics, many proposals take animal communication and language to be evolutionarily related through a gradual process of descent with modification. However, Chomsky has persistently contended that language could not evolve from animal communication.

The extensive study of animal communication systems has revealed highly complex communicative behaviors that make use of truly referential signals, like those of bees. In addition, animals like birds, whales, bats, etc., possess combinatorial systems that somehow resemble that of language, for they are arranged according to several levels of structure (Berwick et al. 2011).

Despite the great complexity of animal communication, its properties are very different from those of language (Longa 2012). For instance:

1. Animal communication is restricted to the expression of biological needs (food, danger, mating), whereas language makes it possible to communicate any event.
2. Animal signals are restricted to "the here and now" (Hauser et al. 2002, p. 1576), while language may refer to past or future events.

3. Animal signals trigger a unique response: when a monkey hears an alarm call of a conspecific, the only possible response is to escape. This points to a rigid functional association between the signal and the danger the signal refers to. That association does not apply for language: language does not evoke reactions, but properties (Bickerton 1990).
4. Animal communication depends on sensory perception (i.e., experience), but language makes it possible to refer to everything, even in the absence of prior experience. Therefore, language is a powerful representational system, according to which any concept/event (even an unreal one) may be represented and expressed. This means that language constructs our reality but constructs unreality as well. For this reason, it has a key role in human creativity.
5. Animals do have sophisticated concepts, but most of them cannot be expressed to conspecifics: a barrier exists between cognition and communication. That barrier is absent in humans: everything we can represent can be communicated to others.
6. While animal concepts keep a referential relationship with objects/events in the world, human concepts and words lack the relation to mind-independent entities that defines animal signals (Berwick and Chomsky 2016, p. 84). An apparently simple concept like *book*, which seems to point to a real referent, may nevertheless apply to many situations that reside in the mind, not in the environment: a book that has never existed, etc.
7. Although some animal systems have a combinatorial nature that may somehow resemble that of language, those systems lack semantics (see Berwick et al. 2011, p. 118).

Because animal systems "are radically different from human language in structure and function" (Berwick and Chomsky 2016, p. 63), language seems to be biologically isolated. Accordingly, Chomsky (1968) contended that language is a biological emergence, which can hardly be explained through a process of Darwinian descent with modification from animal

communication. A question becomes very relevant: Is language an overall emergence? Not really, according to more recent stages of Chomsky's thought.

Is Language a Unique Trait or Is It Based on Mechanisms Shared with Other Species?

Hauser et al. (2002) propose a divide between faculty of language in the broad sense (FLB) and in the narrow sense (FLN) as a useful methodological tool for guiding research on language evolution. According to these scholars, language is not a monolithic trait, but something like a mosaic, composed of many different components that are evolutionarily superimposed. The divide makes it possible to analyze the evolutionary history of each component, aiming at determining which components are shared with other species and which ones are not. The features that can be thought of as being inherited unchanged from a common ancestor, or subjected to minor modifications, are said to be part of FLB, while the qualitatively new components are said to be part of FLN. Therefore, FLB gathers all the capacities necessary for language that are neither specific to language nor to humans, whereas FLN covers those capacities which are unique to language and to humans.

From the comparative evidence, Hauser et al. (2002) suggest that main mechanisms of the A-P and C-I modules have clear homologues in animals, those mechanisms long predating the emergence of language. The opposite applies for the computational system: this is the only evolutionary novelty and the only component of FLN. A second contention of Hauser et al. (2002) is about the specific contents of FLN: its only component is recursion, i.e., the procedure the computational system makes use of, with its open-ended generativity based on the structural embedding of hierarchically organized phrases. The search for a syntax-like system in animals, whether wild or trained, has been fruitless. Apes appear to be able to acquire symbolic systems, at least under experimental conditions, although no primate has ever been able to acquire a full-fledged language or even rudimentary versions thereof involving combinatorial syntax. This

suggests that FLN is unique to the human species (Hauser et al. 2002, p. 157).

What Has Evolved, Then?

Because FLN lacks any kind of homologues, the computational system had to emerge in the course of human evolution. It is necessary to shed light on what the computational system consists of, given that its very nature will determine the range of hypotheses about its evolution.

From the view of the Minimalist Program, the computational system is mainly reduced to a single operation, named Merge, which applies recursively, giving rise to hierarchical structures through the merging of two syntactic objects (lexical items, affixes, or groups of lexical items) into a new object. One of the two elements becomes the head of the resulting structure. For example, a sentence like *John will read the book* derives from these successive applications of Merge (specific details omitted):

Merge 1: {the, book}

Merge 2: {read, {the book}}

Merge 3: {will, {read the book}}

Merge 4: {John, {will read the book}}

The conclusion can be reached that FL is very simple: it basically derives from a single operation, the conditions of which are simple as well (Longa et al. 2011, p. 599):

1. Binary branching: Merge combines two elements instead of three, four, etc. This greatly reduces the computational complexity.
2. Asymmetric labeling: the outcomes of Merge become identified with one of the two merged elements, not with both of them or with a different one; the projection of a noun produces a nominal phrase, etc. This means that asymmetric labeling presupposes headedness (endocentricity).
3. Structural preservation: each successive application of Merge preserves the structure obtained so far. This condition is computationally efficient: it leaves the two syntactic objects unaltered.

4. Unboundedness: Merge operates in an unlimited way (limitations are due to short-term memory, attention, etc.).

Merge, at the heart of FL, is according to Chomsky the only specifically linguistic and specifically human component of language emerged in evolution. Combined with the prior infrastructure (FLB) and with the appearance of the lexicon (a deep mystery for Berwick and Chomsky 2016), Merge led to language emergence. This is the main contention of Hauser et al. (2002): a specific novelty linked to pre-existing components. The proposal fits in well with evolutionary dynamics (see Chomsky 2010; Berwick and Chomsky 2016): evolution is something like a tinkerer that operates by adding slight modifications on previous systems: “Evolution does not produce novelties from scratch. It works on what already exists” (Jacob 1977, p. 1164).

How Did FL Emerge?

Merge is taken to be the evolutionary key of language (Berwick and Chomsky 2011, 2016; Chomsky 2007, 2010). What evolutionary event gave rise to it? Chomsky’s answer is that Merge first arose in the domain of thought, and was subsequently exapted for language (Chomsky 2010; Berwick and Chomsky 2016), this view implying an evolutionary asymmetry (see below).

More specifically, Chomsky suggests that Merge could have arisen through some slight rewiring of the brain produced by a genetic event, “presumably a small mutation” (Chomsky 2007, p. 14). The mutation could have taken place in an individual pertaining to some anatomically modern human small breeding group from East Africa, from which we are all descendents, this claim deriving from the essential uniformity of FL in the species. However, it should be emphasized that Merge arose in the domain of thought and consequently gave rise to an inner language. Merge led to a substantial modification of the simple system of thought existing so far, based on elementary schemata, and allowed to generate an infinite array of internal expressions made up from (already available) lexical items. The individual who experienced that mutation was

endowed with many advantages, like “capacities for complex thought, planning, interpretation, and so on” (Chomsky 2010, p. 59). Then, the mutation could be transmitted to the offspring also as an internal capacity, in such a way that it began to proliferate among the group.

When that internal capacity spread over the population, “there would be an advantage to externalization” (Chomsky 2010, p. 59). Perhaps through a mutation, such an internal capacity was linked as a secondary process to the A-P system in charge of externalization, intact for hundreds of thousands of years. When the complex language of thought became externalized, FL emerged in its current sense.

To summarize, three stages were involved: (1) a simple system of thought; (2) at a given point, the appearance of Merge produced a linguistically structured system of thought; (3) that system of thought became externalized, giving rise to FL, the specifically linguistic and specifically human component of language. The slight rewiring of the brain triggered by the mutation had nevertheless great effects (FL) because the vast majority of ingredients for language were already in existence.

When Did Language Emerge?

The appearance of FL happened after the speciation event that produced our species, FL consequently being an evolutionary result linked to anatomically modern humans. Its emergence may be dated within a narrow evolutionary window, a timespan between 200,000 and 60,000 years ago (Berwick and Chomsky 2016, p. 110), before the great exodus from Africa. More specifically, it could have taken place more than 80,000 years ago, if the wide symbolic record found in sites like Blombos Cave (South Africa) is considered (Berwick and Chomsky 2016, p. 87). The reason for such a dating is not unknown to paleo-anthropologists (for a review, see Balari et al. 2013): many of them consider that modern behavior arose in that period, including many instances of symbolism (several forms of art, ornaments, engravings, burials with offerings, music), technology unknown to date, etc. Those proxies reveal an unprecedented cognitive flexibility and a

powerful creativity, both factors being very unlikely in the absence of language, which makes it possible to build any kind of mental models (Dennett 1996). Therefore, the emergence of FL is for Chomsky the obvious candidate for those behavioral changes to be explained. The aforementioned proxies would be a visible effect of the externalization of thought, thus indicating the full emergence of language. To summarize, the evidence suggests that (1) FL is a recent evolutionary outcome and (2) it arose in the African Middle Stone Age about 100,000–80,000 years ago.

Why Does Language Imply an Evolutionary Asymmetry?

An evolutionary asymmetry exists between the two interfaces of FL (Berwick and Chomsky 2016, p. 71; Chomsky 2010, p. 55). If we keep in mind that the previous stage to FL was an internal language of thought, the said asymmetry implies that the interface of FL with the C-I system is primary, while the interface with the A-P system (related to externalization) is secondary (although by no means crucial for language to exist). In fact, FL exhibits an optimal relation with the C-I system, for language is just externalized thought (Longa et al. 2011). From this view, there is only one internal language in the species, in charge of generating the expressions of the language of thought.

However, externalization does not hold the same relationship with FL; it is far from optimal, as evidenced by the fact that it causes humans to express common internal thoughts very differently, according to the very disparate mechanisms (case, aspect, agreement, etc.) language makes use of. This secondary process reveals the evolutionary asymmetry, as reinforced by the fact that language is even modality-independent (oral or gestural).

This leads to the question of why there are so many languages if there is just a common internal language of thought. The said asymmetry provides a reasonable answer: the great variation shown by languages is linked to externalization and suggests that this phenomenon is not to do with the biological evolution of language but with

historical and cultural processes (historical change; Chomsky 2010, p. 61), which are very variable and produce heterogeneous results. Therefore, while the computational system is essentially uniform across the species, the morphological and phonological processes that convert hierarchical internal syntactic objects into linearly ordered objects accessible to the A-P system are very different from each other; interlinguistic variation derives from the very disparate solutions to how internal syntactic representations surface in the form of sentences. Thus, language diversity does not lie in the computational system, but in how those internal syntactic objects generated by the computational system become linearized. This is the very task morphology and phonology are concerned with: to map hierarchical internal syntactic objects into linearly ordered strings.

What Is the Role of Natural Selection?

Chomsky has always been reluctant to consider language to have evolved through natural selection, by claiming that “there is no substance to this assertion” (Chomsky 1968, p. 85). This claim should be well understood, because Chomsky does not deny such a mechanism. He acknowledges that “Language must surely confer enormous selectional advantage” (Chomsky 1980, p. 239). However, one thing is to argue that a trait has an adaptive value and a quite different thing is to assume that it is the adaptive value that has driven the evolution of the trait. Actually, Chomsky distinguishes two roles of natural selection: (1) as a creative process which according to Neo-Darwinism is the only mechanism responsible for complex design and (2) as a process which just sifts the results generated by other means. Chomsky rejects the former sense and accepts the latter one. From this view, natural selection would be a “coarse filter that rejects the utter failures” (Goodwin 1994, p. 157). This amounts to saying that “natural selection works on already developed outcomes (so it can not have caused those outcomes)” (Gottlieb 1997, p. 17). Accordingly, evolutionary novelties, like Merge (slight, although endowed with far-reaching consequences) arise abruptly, although they will need

to be sifted by the process of natural selection (see Berwick and Chomsky 2016, ch. 1). To summarize, FLN is not the product of prolonged and gradual evolutionary development driven by natural selection. In addition, that possibility does not fit in well with the brief interval of time within which language evolution appears to have occurred.

Was Communication the Selective Pressure That Guided Language Evolution?

The aforementioned evolutionary asymmetry illustrates a core idea of Chomskyan thought that strongly departs from an adaptive view of language. Adaptationism considers that the traits evolved through natural selection adapt organisms to their environments, thus solving specific needs. Therefore, for adaptationism it is crucial to suggest a selective pressure that guides the evolution of the trait and provides practical, adaptive advantages. As regards language, approaches which aim to explain language origins as an adaptation underline its communicative advantages (Pinker and Bloom 1990), assuming that a selective pressure towards more efficient communication was the driving force that guided language evolution.

Chomsky rejects that view: language did not emerge linked to communicative needs, for communication was a secondary process, derived from externalization. In fact, the idea that the main function of language is communication cannot be sustained, because language, as humans experience it, serves multiple purposes: to communicate thoughts, to be sure; but also to assert the mere presence of an interlocutor, to lie, joke, express beauty, to talk to oneself, to describe instances of nondenumerable expressions in mathematics, and surely many other purposes that any reader can fathom. Any of those is a “function of language,” though none of them seems more natural than the others. Accordingly, “The functions of language are various” (Chomsky 1980, p. 230). Had a function of language to be emphasized, it would be its use for internal thought, because the appearance of Merge gave rise to language as an internal tool, something like a cognitive glue that binds together other

cognitive systems (Berwick and Chomsky 2016, p. 111). Therefore, any approach mainly based on communication is “seriously misguided” (Chomsky 2010, p. 61): if communication is taken to be the driving force in language evolution, then an animal communication-like system would suffice.

Some Criticisms

To summarize in a few paragraphs the main criticisms of the Chomskyan treatment of language evolution (and language) would be impossible, for many approaches strongly disagree with such a treatment (for a wide picture of current approaches on language evolution, see Tallerman and Gibson 2012). For that reason, this section will briefly raise several criticisms that, nevertheless, share the computational approach on language Chomsky adheres to.

According to this scholar, FL is a uniquely human capacity that consists of a specifically linguistic computational system, uniquely involved in language. Therefore, the notion of Merge is taken to be part of the universal grammar (Chomsky 2007, p. 7), the genetic equipment for language. However, doubts can be raised about the alleged specificity of FL: Balari and Lorenzo (2013) contend that the biological machinery of language is neither specifically human nor specifically linguistic. Language emergence would be just one of the far-reaching consequences of a slight modification operated on an ancestral architecture shared with many other vertebrates. According to Balari and Lorenzo (2013), the computational system (named the central computational system) is an unspecific device, used not only by language but also by many other motor or cognitive tasks humans are engaged in (see also Longa 2013). These scholars also claim that the computational system language makes use of is not specifically human; actually, many vertebrates share it, the difference being the amount of computational memory associated with such a system (no memory, a basic memory, or a sophisticated one) that produces several types of computational regimes. The more memory the system has at its

disposal, the more computational power it is endowed with. Linguistic computations are context-sensitive, and accordingly they require powerful memory resources.

This view of the computational system makes sense from a neuroanatomical and evolutionary perspective. Currently, it is clear that the neuronal substrate of the computational system relies on the coordinated activity of both cortical and subcortical brain areas. The unspecific view finds support in the basal ganglia grammar model (Lieberman 2006, p. 207 and ss.). This model characterizes a system composed of circuits that participate, among other tasks, in the motor programming of speech, sentence comprehension, or walking and is comprised of two components: an iterative sequencing device (cognitive/motor pattern generator) located in subcortical areas (basal ganglia) and a working memory component located in cortical areas. It is not difficult to link both components to the computational approach: the differences between the several computational types do not reside in the computational system itself, but in the amount of memory the system is endowed with. Therefore, a common computational system has been combined with a greater or lesser working memory space in different species, depending on the development of the cortex.

For the computational system to be operative, it needs to be connected to some external modules supplying their input and capable of receiving their output. The same unspecific computational system may be thus connected to different modules in different species. This means that the connection of FL with the A-P and C-I systems in humans may be a contingent, i.e., accidental fact.

Therefore, there would be two axes of variation, one of them corresponding to the working memory space the computational system has access to and the other axis corresponding to the number/kind of external modules the system interfaces with.

To summarize, according to this approach, the notion of FLN is not a useful one, for the computational system is neither specifically human nor specifically linguistic, although language can still be considered a species-specific innate trait, this specificity resulting from how its several

components are integrated. FL has not developed a specific machinery but uses a system shared with many other animals. A slight change involving an increase in working memory produced a dramatic qualitative change in humans, by which the access to a computational power unknown to date in other species was reached.

Another problematic idea of the Chomskyan approach is the genocentric stance it adheres to. Since its inception, this approach has assumed the need for the universal grammar or linguistic genotype, the genetic principles that make language acquisition possible. The same geneticism is also assumed for phylogeny, for Chomsky contends that Merge, the key of language, arose through a genetic mutation, and thus became part of the universal grammar (see Berwick and Chomsky 2016).
